About the Editors

Dov Cohen, PhD, is Professor of Psychology at the University of Illinois, where he is also affiliated with the College of Law, the Center for East Asian and Pacific Studies, and the Center for Latin American and Caribbean Studies. He is a Fellow of the Association for Psychological Science and the Society for Personality and Social Psychology. Dr. Cohen's research interests include culture, religion, and socioeconomic issues, with studies on violence, law and social policy, consumer finance, creativity, and syndromes of honor, face, and dignity.

Shinobu Kitayama, PhD, is Robert B. Zajonc Collegiate Professor of Psychology at the University of Michigan. He studies psychological diversity across cultures and has pioneered the field of cultural neuroscience. Editor of *Journal of Personality and Social Psychology: Attitudes and Social Cognition*, Dr. Kitayama is a recipient of Fulbright and Guggenheim Fellowships, the Scientific Impact Award from the Society of Experimental Social Psychology, and the Career Contribution Award from the Society for Personality and Social Psychology. He is a member of the American Academy of Arts and Sciences and a Fellow of the Association of Psychological Science.

INTRODUCTION

Young and Still Developing

Five Themes

Dov Cohen and Shinobu Kitayama

We have witnessed many exciting developments in cultural psychology over the past decade. They are grouped into five main themes: (1) the integration of culture and biology; (2) the expansion of cultural approaches into religion, social class, subcultures, and race; (3) the growth of research in application and intervention; (4) the continued emphasis on the re-creation of culture through the everyday practices, habits, and ways of being that help flesh out a cultural logic; and (5) methodological innovation and sophistication. Perhaps the best testament to the growth of the field, however, is its youth, as cultural psychology continues to attract young people who will take the field into the future.

People who write novels hope their work will stand the test of time. People who write for handbooks don't.

When the first edition of this handbook came out, we and our fellow contributors hoped it would quickly become outdated and obsolete.

We hoped it would be outdated because cultural psychology would grow and the state of knowledge would expand so much that new reviews of the field would be needed. We hoped it would be obsolete because the cultural perspective would so pervade mainstream psychology that there would be no need to demarcate a separate field. Culture would be so woven into psychology research that all studies would have a culturally informed perspective, even if they were not explicitly cross-cultural.

The first edition has certainly become outdated. As will be seen, culture research has come pouring out in the previous decade. Chapters in “staple” areas—cognition, motivation and emotion, and the acquisition of culture—needed major updating. A chapter in the first edition was the first to introduce the term “cultural neuroscience”; now the field by that name is so thick with findings that the chapter had to be quite extensive. Entirely new lines of work grew as well. Of the 32 chapters in this edition, about half are on entirely new topics, including, for example, chapters on innovation, terrorism, money, negotiation, health, wisdom, consumer behavior, and so on.

Thus, the first edition certainly got old before its time. Obsolescence was a more ambitious wish. That was not achieved, yet the progress has been remarkable. Culture research has gone from being a rebellious teenager to a respected member of the establishment—not because it has changed but because mainstream psychology recognized that it had something important to say. This process has occasionally been grudging and fitful, but it has proceeded nonetheless. Culture researchers now occupy high-level positions at major journals, and culture research is routinely published in many mainstream outlets including *Science*, *Proceedings of the National Academy of Sciences*, *Journal of Personality and Social Psychology*, *Psychological Science*, and *Developmental Psychology*, just to name a few.

Perhaps someday we will achieve obsolescence and there will be about as much need for a *Handbook of Cultural Psychology* as there is for floppy disks, phone books, and spittoons. We hope this handbook is a step toward its own obsolescence. That may not happen soon, but we can still hope. In the meantime this second edition charts the growth of the field since the first edition and, we hope, paves the way forward.

Like many systems, the growth in cultural psychology has been bottom-up—unplanned, uncoordinated, and proceeding in many different directions at once. But like many adaptive systems, it is also self-organizing, coming together in ways that reflect the environment it is in and the challenges it faces. Below, we summarize five themes that seem to organize many of the exciting developments over the past decade. Each runs throughout many chapters of the book.

CULTURE AND BIOLOGY

One of the most salient themes has been the integration of culture and biology. As Kashima ([Chapter 2](#)) writes in one of the first chapters, culture has been “naturalized.” The capacity for culture and the transmission of knowledge across time and space may be the greatest gift of our human nature. Chapters in this volume cover the co-option of biological systems (Rozin, Ruby, & Cohen, [Chapter 17](#)), the processes by which culture gets “embrained” (Kitayama, Varnum, & Salvador, [Chapter 3](#)), genetic vulnerabilities and gene \times culture interactions (Chentsova-Dutton & Ryder, [Chapter 14](#); Kim & Lawrie, [Chapter 10](#); Kitayama et al., [Chapter 3](#)), and the coevolution of genes and culture (Mesoudi, [Chapter 5](#); also Henrich, 2015). Biomarkers of health also feature prominently in some of the chapters (Kitayama et al., [Chapter 3](#); Kraus, Callaghan, & Ondish, [Chapter 27](#); Miyamoto, Yoo, & Wilken, [Chapter 12](#)). Just as nature versus nurture became nature through nurture, culture and biology are coming together in some intriguing ways. While culture is naturalized, nature is nurtured through culture to make one fully human.

Obviously, bringing in physiological measures and neuroscience provides a more complete picture of how humans respond to their environment. And Kitayama et al. ([Chapter 3](#)) also point out a number of ways we stand to gain from importing neuroscience and physiology into our studies:

1. The cumulative effects of socialization take place over time. “Snapshots” of people in situations cannot capture this. However, experience over time leaves its mark in patterns of neuronal firings (neurons that fire together, wire together), inflammation responses, and genes turned on or off (Kitayama et al., [Chapter 3](#); Miyamoto et al., [Chapter 12](#)). One could say these physiological markers thus provide a “natural history” of socialization.

2. Behaviors and self-reports are often constrained in ways that physiology often is not, giving us a window into what is happening under the surface. Not all, but some of these windows let us know about participants’ initial, very quick responses, before they are “edited” by more conscious processes.

3. Neuroscientific and other studies can also inform us about psychological processes that people could not tell us about even if they wanted to. People do not have access to some cognitive or emotional processes simply because they cannot introspect about them (Wilson, 2002) or defensively will not let themselves introspect about them (D. Cohen, Kim, & Hudson, 2017).

Cultural psychology clearly stands to gain from the import of biological understandings and methods. However, this is also an area in which cultural psychology has its greatest export value. Neuroscience studies, and biological studies more generally, often implicitly have strong universalistic assumptions. Scan the brains of 15 sophomores from Iowa and you see what a particular part of the *human* brain does; in mainstream work, bodies and brains are presumed to work pretty much the same way all over. Contrary to this currently prevailing assumption, however, new evidence shows that brain and body responses are culturally conditioned. Unlike in the U.S., anger may not be so bad for your health in Japan. The part of the brain that thinks about the self (for Westerners) may be the part that thinks about the self, one's mom, one's spouse, and the kids (for Easterners). And the "heritability" of some trait or ability or the seriousness of a risk factor may depend as much or more on the environment as it does on the underlying biology (Kitayama et al., [Chapter 3](#); Nisbett, [Chapter 7](#); Chentsova-Dutton & Ryder, [Chapter 14](#); see also Falk et al., 2013; LeWinn, Sheridan, Keyes, Hamilton, & McLaughlin, 2017; Tucker-Drob & Bates, 2016).

Cultural psychology can become a paradigm-shifting force within psychology. It can potentially also become a paradigm-shifting force within neuroscience. More generally—and to the extent the data warrant it—cultural neuroscience may help in "taking back" the brain and the body from the biological scientists. The dominant way of thinking about adult brains and genes—among scientists and especially in the American public—is to regard them as biological blueprints that determine (or at least greatly influence) human behavior: People do things because their brains and their genes tell them to (Heine, 2017). To the extent that cultural psychologists show that experience (culture) shapes the brain and expression of genes, it may bring our understanding back toward a more moderate position—in which we shape our brains and genes, in addition to their shaping us.

Where the next great strides in biology will come from is unclear. Perhaps the next great breakthrough will come in the study of the human microbiome. If so, we might unite the study of gut bacteria with the topic of some of cultural psychology's finest ethnographic and experimental work—food (Rozin et al., [Chapter 17](#)).

EXPANDING THE TERRITORY COVERED BY THE “CULTURAL”

A second development has been the widening expanse of the cultural. In recent years, there has been an embrace of the idea that there are indeed “many forms of culture” (A. Cohen, 2009, 2014), including, for example, religion, race, social class, and subcultures (A. Cohen & Neuberg, [Chapter 32](#); Mendoza-Denton & Worrell, [Chapter 28](#); Kraus et al., [Chapter 27](#); Rentfrow & Jokela, [Chapter 29](#)). The explosion of research on social class has probably made class the “form of culture” that has seen the biggest growth in the past decade. There are a variety of ways to examine social class (Wright, 2008). Kraus et al. ([Chapter 27](#)) outline and integrate several perspectives, but ideas about social class or socioeconomic circumstances run throughout various chapters (including those by Markus & Hamedani, [Chapter 1](#); D. Cohen, Shin, & Liu, [Chapter 22](#); Miyamoto et al., [Chapter 12](#); Nisbett, [Chapter 7](#); Kitayama et al., [Chapter 3](#)). As the world most of us researchers live in (that of the upper-middle class) grows more and more separate from everyone else (Murray, 2012) and as everyone else gets tired of feeling left behind with stagnating wages, insecure jobs, and inadequate credentials, understanding issues of social class becomes more and more urgent (D. Cohen et al., [Chapter 22](#); D. Cohen, Shin, & Liu, 2019; D. Cohen, Shin, Liu, Ondish, & Kraus, 2017).

Research on subcultures has also deepened. As immigration remains an electrified “third rail,” as refugee crises emerge, and as nationalistic movements appear across the West, knowledge about subcultures becomes more important. It should not be surprising then that the topics of acculturation, immigration, and cultural acquisition have captivated researchers and produced work that has fascinated the field (Keller, [Chapter 15](#); Leung & Koh, [Chapter 21](#); Morris, Fincher, & Savani, [Chapter 18](#);

Mesoudi, [Chapter 5](#); Rentfrow & Jokela, [Chapter 29](#); Mesquita, De Leersnyder, & Jasini, [Chapter 19](#)). Pioneering work in this area was done by John Berry, with contemporary work both building on and critiquing Berry's insights, as well as taking the field in new directions entirely.

The topic of race is also getting more attention in cultural psychology. Amazingly, the last *Handbook of Cultural Psychology* (published in the United States) did not have a chapter on “race”—probably the single largest dividing line in American history. “Ethnicity,” at least in contemporary America, sounds innocuous enough. “Race,” however, has always involved relations of dominance and ideas about biologically rooted inferiority. In the United States, of course, race primarily means black and white; and no serious discussion about multiculturalism, diversity, inclusion, or the future of the American project could ever be complete if it did not address this topic. This edition of the *Handbook* has a chapter on race (Mendoza-Denton & Worrell, [Chapter 28](#)). We consider it a start—and we hope, an encouragement to others to do work in one of cultural psychology's most profoundly underresearched topics.

Finally, compared to its massive influence across the globe, religion is also a hugely understudied topic in psychology. If one were to derive a *MOJO ratio*—computed as a variable's MOtivational force in the world ÷ the number of JOurnal pages devoted to it—religion would likely sit at the top of the list.

However, cultural psychologists have been starting to attend to religion as well. Some study little-*r* religion (the antecedents and consequences of generic religious beliefs and organization), but there has also been an expansion of work on big-*r* Religion (the *particular* belief systems, practices, and values that make one religious community different from another). Both types of work are included in this volume (A. Cohen & Neuberg, [Chapter 32](#); Levine, Harrington, & Uhlmann, [Chapter 23](#); Kim & Lawrie, [Chapter 10](#); Atran, [Chapter 31](#); Atran, 2007). Important contributions also include Norenzayan's articles on theodiversity (2016), as well as his book *Big Gods* (2013). The latter describes how large-scale cooperation was facilitated by the emergence of religions with one (or a few) gods who actually cared about what humans did to each other.

For centuries, religion shaped folk understandings of human nature. It also shaped professional psychologists' view of human nature, beginning

with its most famous clinician, Freud. Though he aspired to universalism, Freudian psychology was—as the president of the American Psychiatric Association once said—“Calvinism in Bermuda Shorts” (Kim & Cohen, 2017). It was saturated with a Puritanism that was likely difficult to notice during the Victorian Era (Reiff, 1961, 1990). Whatever one may say about his methods, Freud was clearly a giant and a very astute psychologist—in fact, a cultural psychologist, though he may not have realized it. Some of his hypotheses about people sublimating forbidden desires into creative work or turning forbidden feelings into their opposites have recently been borne out in experimental research—though “Protestants” should be substituted for the word *people* (D. Cohen, Kim, & Hudson, 2014, 2017). But, this is only one example of recent cultural work examining the effects of big-R religion, as particular religious traditions seem quite influential in shaping valuations of emotions (Tsai & Clobert, [Chapter 11](#)), individualist–collectivist orientations (A. Cohen & Neuberg, [Chapter 32](#); see Markus & Conner, 2014), workways (Levine et al., [Chapter 23](#)), foodways (Rozin et al., [Chapter 17](#)), wisdom (Grossmann & Kung, [Chapter 13](#)), conceptions of purity and divinity (Miller, Wice, & Goyal, [Chapter 16](#)), ingroups and outgroups (Mesquita et al., [Chapter 19](#)), and of course, the motivations of devoted actors participating in religious or ethnoreligious warfare (Atran, [Chapter 31](#); A. Cohen & Neuberg, [Chapter 32](#)).

Almost surely this expansion of cultural topics—into big-R and little-r religion, social class, subculture and acculturation, and race—will continue. This should be true because of the fascinating work cultural psychologists have produced so far. It should also be true because these topics are all highly related to what some see as a future growth area for cultural psychology—namely, explorations of power dynamics and intergroup relations (Markus & Hamedani, [Chapter 1](#); Miller et al., [Chapter 16](#); A. Cohen & Neuberg, [Chapter 32](#)). Finally, this research should continue because headlines keep pushing these topics into the forefront of national and international conversations. If religion threatens to create civilizational fault lines; if have-nots feel increasingly left behind; if immigration issues, separatist movements, revanchism, and refugee crises continue to rile nation-states; and if backlashes and white nationalism intensify, then these topics will continue to capture researchers’ attention and seem more urgent to study.

REAL-WORLD APPLICATIONS: ORGANIZATION, HEALTH, MONEY, AND BEYOND

Cultural psychology has also expanded its focus from “basic” research, with an increasing emphasis on application and intervention. The division between “basic” and applied may be seen as relatively artificial. This is what one would expect from any discipline that partially has its roots in social psychology. The founder of social psychology, Kurt Lewin, is credited with various dicta, among them (1) “There is nothing so practical as a good theory” and (2) “If you want to understand something, try to change it.”

The spread into applied work can be seen just in the chapter titles. Since Hofstede’s (1980) landmark work, studies of culture have often had some connection to studies of commerce. Here, these connections are fleshed out in chapters on work, innovation, money, consumer behavior, and negotiation (Levine et al., [Chapter 23](#); Chiu & Hong, [Chapter 26](#); D. Cohen et al., [Chapter 22](#); Shavitt, Cho, & Barnes, [Chapter 25](#); Gelfand & Jackson, [Chapter 24](#)). But the applications go beyond this area and extend to topics such as terrorism, health and well-being, and cultural learning and adjustment (Atran, [Chapter 31](#); Miyamoto et al., [Chapter 12](#); Morris et al., [Chapter 18](#); Oyserman & Yan, [Chapter 20](#); also see Tov & Diener, 2007). We have broken out cultural learning as its own “staple” topic in cultural psychology, but Morris et al. and Mesquita et al. ([Chapters 18](#) and [19](#), respectively) illustrate how arbitrary some of these classifications actually are. Both cover very practical questions about adjustment to new cultures—by immigrants or by sojourners—though one has a decidedly emotional focus (Mesquita et al., [Chapter 19](#)), whereas the other is more cognitive (Morris et al., [Chapter 18](#)).

In terms of intervention studies, some of the most exciting work in the social sciences in the past decade has involved controlled trials done by economists. Many of the economists’ studies involve creating interventions to help the poor of the developing world and comparing participants randomly assigned to the intervention versus control conditions. Such research has upended much of what we thought we knew about the world’s poor and how we might tailor policy and intervention to help them (Banerjee & Duflo, 2011a, 2011b; D. Cohen et al., [Chapter 22](#); Collins, Morduch, Rutherford, & Ruthven, 2009; Morduch & Schneider, 2017).

Unfortunately, although Lewinian “action research” should be considered the birthright of sociocultural psychologists, we have been surprisingly uninvolved in many of these intervention studies. There are exceptions. For example, there have been culturally informed interventions designed to facilitate the adjustment of nonwhite college students to majority-white college campuses or to help first-generation college students who might otherwise feel out of place in the individualistic, expressive ethos of most universities (Mendoza-Denton & Worrell, [Chapter 28](#); Markus & Hamedani, [Chapter 1](#); Miyamoto et al., [Chapter 12](#); also Oyserman, 2015). However, these intervention studies have been relatively rare. This represents an area in which cultural psychology has much more room to grow. Such studies are not “low-hanging fruit.” They are the opposite of the quick, easy, and cheap Internet and Mechanical Turk studies that have been proliferating in psychology. These intervention studies are time-consuming, expensive, and difficult to run (see Karlan & Appel, 2016; D. Cohen, [Chapter 6](#); D. Cohen et al., [Chapter 22](#)). However, they offer a potentially huge and important payout—one that, we hope, compensates for all the toil, tears, and sweat.

A MOSAIC PICTURE OF CULTURE

The field has also been less Mosaic, and more mosaic. That is, “Mosaic” (which means of or relating to Moses and his laws) and “mosaic” (meaning, a picture created out of the patterning of smaller, diverse elements) represent two very different approaches to culture. In the former, one might describe cultures in terms of an abstract set of values, sacrosanct and delivered from on high, as if from Moses walking down the mountain with the 10 commandments. One learns about these key abstract values by asking people about them and having people rate or rank them. The values are articulable, and people can clearly order them in terms of importance. The list of possible values is relatively small and reasonably universal, though cultures differ in how people rank them. Individuals within a culture differ, though there is likely some rough consensus. Behaviors in most situations can be predicted by consulting this value ranking and determining what behavior maximizes the most important value(s).

There is much to be said for this approach. It has been foundational, generative both within and outside psychology, clear-eyed, and foresighted. It boils down what a culture believes is important to a manageable set of dimensions, facilitates comparisons of similarities and differences across cultures, and is extremely parsimonious, potentially allowing one to predict a wide array of behaviors by knowing a relatively small amount of information about how core values are ranked. The contributions from this approach have been—and continue to be—substantial (Inglehart & Welzel, 2005; Schwartz et al., 2012; Vauclair & Fischer, 2011).

However, this is not cultural psychology's approach—or at least, not its main approach. It is more mosaic, trying to determine overall patterns or an underlying cultural logic from understanding smaller, concrete elements of a culture (practices, habits, ways of doing) and how they fit together in some sensible, coherent way. It recognizes that there are multiple different cultural logics that can coherently organize a social world, that values can be instantiated in many different ways according to local meanings and practices, that culture is realized and re-created in the mundane and everyday, and that many important, central ideas are not fully articulable—even though it is incredibly important to find out what people think they are doing (Geertz, 1983; Markus & Hamedani, [Chapter 1](#)). Studies in cultural psychology do not necessarily begin bottom-up (D. Cohen, [Chapter 6](#)), but they assume cultures are mostly constructed that way—through the sometimes harmonious, sometimes messy meshing of ideas, rituals, beliefs, interactions, conflicts, institutional and situational affordances, public knowledge, and private understandings and misunderstandings about the social order (D. Cohen, Liu, & Shin, in press).

Cultural psychology examines practices, habits, ways of thinking, sleeping, eating, talking, walking, joking, insulting, fighting, relating, preening, playing, praying, getting, spending, and so on. Not only are all these “little” elements of culture worth examining on their own, but it is also important to see how these “little” elements fit together and form (like a mosaic) a big picture—of meanings and patterns, organized by an underlying cultural logic.

To be fair, this emphasis on the mosaic rather than the Mosaic is not a new direction but actually represents continuity rather than change. It is what might be expected from a field where seminal articles have tried to

“extract the moral goods” by examining family sleeping arrangements of who sleeps with who (Shweder, Jensen, & Goldstein, 1995), or by asking the question “Why do men barbecue?” given that women usually do most of the cooking (one answer: because it’s outside rather than within the home) (Shweder, 1993; but see Casserly, 2010; Moss, 2014; Rhodes, 2012).

Cultural psychology has historically been mosaic. However, it is useful to see how this tradition has continued with analyses of practices related to interaction patterns with young infants, food, worship, fighting, working, sharing, shopping, saving, persuading, supporting, talking, noticing, creating, relating, drinking, getting sick, and healing (Keller, [Chapter 15](#); Rozin et al., [Chapter 17](#); D. Cohen et al., [Chapter 22](#); A. Cohen & Neuberg, [Chapter 32](#); Uskul, Cross, Günsoy, & Gul, [Chapter 30](#); Oyserman & Yan, [Chapter 20](#); Levine et al., [Chapter 23](#); Shavitt, Cho, & Barnes, [Chapter 25](#); Loewenstein, [Chapter 9](#); Masuda et al., [Chapter 8](#); Nisbett, [Chapter 7](#); Talhelm & Oishi, [Chapter 4](#); Kim & Lawrie, [Chapter 10](#); Chentsova-Dutton & Ryder, [Chapter 14](#)). In organizing the chapters of this book, we couldn’t have a dedicated, separate section on mosaic approaches to culture, because the section would have swallowed the book.

METHODOLOGICAL PLURALISM AND INNOVATION

Also representing continuity is the field’s increasing methodological innovativeness. Cultural psychology has always been pluralistic in its methods. Notable in the past decade has been the increased use of neuroscientific and physiological measures, techniques of situation sampling, designs measuring person–environment fit, agent-based modeling, and data collected near the front lines of battle (Chiu & Hong, [Chapter 26](#); Gelfand & Jackson, [Chapter 24](#); Mesoudi, [Chapter 5](#); Kitayama et al., [Chapter 3](#); Kraus et al., [Chapter 27](#); Chentsova-Dutton & Ryder, [Chapter 14](#); Morris et al., [Chapter 18](#); Kim & Lawrie, [Chapter 10](#); Atran, [Chapter 31](#); D. Cohen, [Chapter 6](#); Uskul et al., [Chapter 30](#)). The field also continues its critique of how some of psychology’s standard measurement tools are culture-drenched, such as those measuring intelligence, wisdom,

attachment, and morality (Grossman & Kung, [Chapter 13](#); Keller, [Chapter 15](#); Miller et al., [Chapter 16](#); Nisbett, [Chapter 7](#)).

It is unclear where the next methodological innovation will come from, but possibilities include the use of “Big Data” (Stephens-Davidowitz, 2017), better tools for monitoring participants’ attention and experience in real-world settings (e.g., Google glasses; Dietze & Knowles, 2016), the incorporation of augmented reality in experiments, improved modeling techniques or statistical tools for dealing with correlational data, and so on. The payoffs from using these tools are still unknown, and we would be well advised to remember the mantra that “correlation is not causation” and be cautious that “Big Data” might lead to “Thin Description.” “Factoid” understandings of culture will not get us very far. However, we need to keep our eyes open for promising techniques developed in our field and others.

Even the replication crisis—currently rocking the social sciences, as well as medical science and genetics—will do more than simply establish a new set of scientific norms. As noted in [Chapter 6](#), cultural psychologists may profit greatly from the chaos of conflicting studies. Most fields aim for robustness; variation in results is bad. However, in Taleb’s (2014) terminology, cultural psychology as a field is “antifragile”; it gains from variation and disorder. There are many reasons that studies may not replicate, but one is that participant populations are different (Greenfield, 2017; Sternberg, 2017). Effects that hold in one population may not hold in another. This is our field’s bread and butter. However, to prove its worth, cultural psychology has to have more to say than “It’s cultural.” We need to be able to measure the elements of culture that lead to effects occurring in one place but not another. Then we need to test what we learn on new data—ideally (if possible) with a manipulation of the underlying cultural element hypothesized to produce the variation (D. Cohen, [Chapter 6](#)). “Just so” stories will not be enough.

These five themes illustrate some of the important ways the field has grown over the past decade. But there is more that suggests optimism for the field’s future. Perhaps the best testament to the growth of cultural psychology (and its trajectory) may be its youth.

Flipping through the book, readers will likely note a large proportion of citations to relatively new work. This is probably not the best metric of growth and trajectory, however, because (1) new articles can express old

ideas and (2) as editors, we purposely asked authors to especially highlight work done since the last handbook. Perhaps a better metric is the age of the authors. Taking the *senior* authors on all chapters, the median number of years post-PhD was 15. (In contrast, the median for the first edition of the handbook was 29 years post-PhD). Now, of course, (1) new professors can express old ideas, but (2) as editors, we (for the most part) did *not* purposely tilt young in our choice of authors. Those invited to contribute the 32 chapters here were the people we thought were doing some of the most exciting work or could provide the most insightful take on the field.

Fields grow when they attract young people. They die when they don't. Based on what has happened in the past decade and the field's success in drawing in young people, the relative youth of our authors suggests that cultural psychology potentially has many years of expansion ahead.

As a field, cultural psychology is still young and growing—while hoping for its own obsolescence.

CHAPTER 1

People Are Culturally Shaped Shapers

The Psychological Science of Culture and Culture Change

Hazel Rose Markus and MarYam G. Hamedani

The term “culture” is everywhere today as people strive to make sense of their increasingly diverse and divided worlds. To say “It’s cultural,” or “It’s a culture clash,” or “We need a culture change” is becoming idiomatic, and lay cultural theories and hypotheses abound. In this chapter, we review how the psychological science of culture has advanced in the past decade and how psychologists are providing insights to today’s most pressing issues. In the first section, we explain some foundational ideas of the science of cultural psychology, introduce the culture cycle, and summarize how different culture cycles shape different ways of being a person. In the second section, we describe several crosscutting generalizations about people and about culture that have become more fully theorized and empirically grounded since the first edition of this volume was published. In the third section, we review some key empirical insights from the field that have emerged over the past decade. And finally, we consider how to apply some of the insights of cultural psychology to understand contemporary culture clashes and divides, as well as envision psychologically grounded approaches to culture change.

The term “culture” is everywhere. Lay cultural theories and hypotheses abound as people strive to make sense of their increasingly diverse and divided worlds. People invoke culture as they confront problems in education, health, criminal justice, sports, entertainment, business,

economic development, and sustainability, and as they contend with power and inequality in these domains (e.g., racism, sexism, classism, homophobia, imperialism). To say “It’s cultural,” or “It’s a culture clash,” or “We need a culture change” is becoming idiomatic. What precisely counts as “culture” can be geographically based and focus on familiar distinctions—such as the East versus the West, the West versus the Rest, the Global North versus the Global South—but it is also no longer geographically bound. Culture includes other distinctions such as social class or socioeconomic status (SES); race, ethnicity, or tribe; gender and sexuality; region of the country, state, or city; religion; profession, workplace, or organization; life stage and generation; immigration status; and many more (A. Cohen, 2014; Gelfand & Kashima, 2016; Markus & Conner, 2014; Uskül & Oishi, 2018). A “culture” or “cultural context” serves as a label for any significant social category associated with shared ideas (e.g., values, beliefs, meanings, assumptions) and practices (e.g., ways of doing, making, and being) that organize people’s experiences and behavior.

We begin the chapter with a selection of recent findings to highlight the fact that culture matters in every domain of life, and that the cultures under study in the field are an increasingly diverse set, as are the researchers who are the studying them. These findings show how culture is at work in our world sometimes in predictable or understandable ways, and sometimes in surprising or unseen ways. [Figure 1.1](#) highlights recent examples of how cultures influence everyday experience—in school, at work, in the marketplace, on our streets, in our communities, and across borders.

At school

Children in Cameroon are better able to delay gratification and resist a tempting marshmallow than children in Germany (Lamm et al., 2017).

Learners in the United States are more likely to complete an online course when they focus on how to achieve their personal goals than learners in China and India (Kizilcec & Cohen, 2017).

Latinx college students perform better when their family (vs. individual) values are affirmed compared to white college students (Covarrubias, Herrmann, & Fryberg, 2016).

In the workplace

Chinese are more likely to seek the advice of others when making career decisions than Americans (Guan et al., 2015).

To be well regarded by their bosses, Latin American workers are more likely to act warmly (vs. competently) than U.S. American workers (Torelli, Leslie, Stoner, & Puente, 2014).

In the marketplace

Americans contribute more personal opinions and recommendations in online reviews than do Chinese reviewers (Lai, He, Chou, & Zhou, 2013).

Indian consumers are less likely to make product purchases based on their personal preferences than are American consumers (Riemer, Shavitt, Koo, & Markus, 2014; Savani, Markus, & Conner, 2008).

FIGURE 1.1. Culture at work in the world: A sample of recent findings.

This chapter is organized into four sections: (1) cultural psychology: what is it?; (2) what cultural psychologists know about persons and cultures; (3) recent empirical insights and advances; and (4) looking ahead: from culture clashes to culture change. In the first section, we explain some foundational ideas of the science of cultural psychology, introduce the culture cycle, and summarize how different culture cycles shape different ways of being a person. In the second section, we describe several crosscutting generalizations about people and about culture that have become more fully theorized and empirically grounded over the past decade. In the third section, we review some key empirical insights from the field since the first edition of this volume was published. And finally, we consider how to apply some of the insights of cultural psychology to understand contemporary culture clashes and divides, and envision psychologically grounded approaches to culture change.

CULTURAL PSYCHOLOGY: WHAT IS IT?

Mutual Constitution: The Psychological Is Cultural and the Cultural Is Psychological

The studies sketched in [Figure 1.1](#) compare people across a wide range of sociocultural distinctions and divides. Studies like these, and thousands of others, now provide robust evidence for the basic social-psychological insight that *the situation is powerful*. People who experience different social circumstances and situations, what we call here “sociocultural contexts,” as a consequence of nation, social class, race, ethnicity, gender, sexual orientation, generation, profession, and more, are likely to respond to different norms and incentives. They are also likely to understand the world using different interpretive frameworks (also called “construals,” “schemas,” “perspectives,” “mindsets,” “mentalities,” or “meanings”).

Some of psychology’s earliest theorizing reflects a commitment to the ways in which psychological processes are made up of, or are made by, the social elements of a person’s many intersecting contexts (although the term *culture* was not explicitly invoked until later). Wundt, a founding figure in modern psychology, believed that no thought, judgment, or evaluation could be methodologically isolated from its sociocultural base (Graumann, 1986). More explicitly, Lewin (1948), one of social psychology’s intellectual founders, wrote:

The perception of social space and the experimental and conceptual investigation of the dynamics and laws of the processes in social space are of fundamental and theoretical and practical importance. . . . The social climate in which a child lives is for the child as important as the air it breathes. The group to which the child belongs is the ground on which he stands. (p. 82)

As Lewin (1946/1951) also proposed “the person (*P*) and his environment (*e*) have to be viewed as variables which are *mutually dependent upon each other*. In other words, to understand or predict behavior the person and the environment have to be considered as *one constellation of interdependent factors*” (pp. 239–240; emphasis added).

Although social psychology is one of the foundational disciplines for cultural psychology, many social-psychological studies examine the behavior of strangers—often college students—in laboratory-generated situations. This constrained, lab-based analog of the social environment is

designed for the purpose of controlling the situation and specifying which aspects of situations cause behavior change. Cultural psychology research includes comparisons across a wider range of social circumstances, and encompasses more within the scope of “the situation” than has been typical in social psychology. From the wide-angle perspective of cultural psychology, cultures are powerful situations—albeit situations writ larger, longer-term, more complex, and messier than those typically explored in traditional social-psychological studies. One goal of cultural psychology is to specify the multiple intertwining micro, meso, and macro mechanisms through which situations wield their power.

The number of definitions of “culture” rivals the number of cultures themselves (e.g., Kroeber & Kluckhohn, 1952). Heine (2015), in his cultural psychology textbook, draws on Richerson and Boyd (2005) to define culture as “any kind of idea, belief, technology, habit, or practice that is acquired through learning from others. Humans are therefore a cultural species” (p. 7). Morris, Chiu, and Liu (2015a) define culture as a system: “Culture is a loosely integrated system of ideas, practices, and social institutions that enable coordination of behavior in a population” (p. 632). Some theorists (Adams & Markus, 2004; Shweder, 1991, 2003) have returned to the insights of Kroeber and Kluckhohn (1952), who highlight the ongoing *mutual constitution* of cultures and psyches:

Culture consists of explicit and implicit *patterns* of historically derived and selected ideas and their embodiment in institutions, practices, and artifacts; cultural patterns may, on one hand, be considered as products of action, and on the other as conditioning elements of further action. (as summarized by Adams & Markus, 2004, p. 341; emphasis in original)

This definition conceptualizes culture as a system or as a cycle—a recurring sequence of interrelated activities that reflect and reinforce each other. The sequence here is made up of sociocultural patterns that condition people’s actions, and people’s actions, in turn, reinforce and change cultures. In the words of this chapter’s title, *people are culturally shaped shapers*.

Throughout the chapter, we use the terms “culture” and “cultural” for simplicity’s sake. Yet the term “sociocultural” is probably preferable for communicating the full scope of cultural psychology (Markus & Hamedani, 2007). A “cultural analysis” as we define it includes both the conceptual and the material aspects of culture. It includes both *meanings*—ideas, images,

representations, attitudes, values, mindsets, schemas, and stereotypes—and what is often treated separately, *the structural and the material*—cultural products, interpersonal interactions, and formal and informal institutional practices, policies, norms, and rules of all types. Likewise, we often use the phrase “sociocultural context” in place of the term “culture.” The term “culture” is sometimes used to convey something more fixed, monolithic, or bounded than intended here. A “sociocultural context” is meant to convey a system with some patterning and organization, but with more dimensionality, more openness, more malleability, more variation, and less coherence.

Cultural patterns condition people’s food and festivals, but significantly, for psychologists, they also condition people’s thoughts, feelings, and actions. As such, *the psychological is cultural*. Humans require multiple intersecting cultures to become people. Cultural transmission is more than just a matter of exposure, learning, and norm-following. Cultural formations of all sorts offer invitations for how to live and how to be. In turn, people often accept these invitations and their associated meanings and expectations so as to identify, affiliate, and belong to various cultural groups (Kashima, 2016; Shweder, 1991; Tomasello, 2011, 2016). As people adapt to the resources, requirements, and norms of different situations and circumstances, which have different requirements, incentives, and meaning-making tools, their psychologies become different. This means that cultures and situations do more than just *influence* people; rather, they give rise to particular psychological and behavioral *patterns*. Situations and cultures are in fact not separate from people. They constitute them or make them up.

With a cultural psychological approach to culture, the focus is on how psychological processes can be implicitly and explicitly shaped by the situations, worlds, contexts, or sociocultural systems that people inhabit. Culture from this perspective is not just about groups of people—the Japanese, the Americans, the whites, the Latinx Americans, the working class (although it can be; see Heine, 2015). Rather, the focus is on how the implicit and explicit patterns of ideas, institutions, practices, and artifacts that make up culture shape behavior, and, in turn, how people’s actions reinforce or disrupt these patterns.

Just as the psychological is cultural, *the cultural is also psychological*. Sociocultural contexts do not exist apart from people. Most aspects of

sociocultural environments are the products of human agency. They are repositories of previous psychological activity, the psychological externalized or made objective in the world. Institutional structures and their products have intellectual history and shared theories and beliefs built right into them. And, in turn, these sociocultural contexts afford future psychological activity. Humans are *Homo sapiens*, those who make sense or meaning, and are also *Homo faber*, those who make or create. Indeed, the fact that humans make the cultures that influence them is a major evolutionary advantage (Henrich, 2015; Mesoudi, 2009; Richerson & Boyd, 2005). Culture thus exists both “in the head” and “in the world,” which means that culture interacts not only with the psychological via the “heads” of people engaging in a particular context, but also via the material “worlds” that people inhabit (Shore, 1996).

A brief answer to the question “Cultural psychology: what is it?” is “research that examines the ways in which cultures and psychologies make each other up in an ongoing dynamic of mutual constitution” (Adams & Markus, 2004; A. Fiske, Kitayama, Markus, & Nisbett, 1998; Gelfand & Kashima, 2016; Kashima, 2000, 2016; Markus & Kitayama, 2010; Shweder, 1991, 2003; Wertsch & Sammarco, 1985). In the next section, we discuss how to represent and map this cycle of mutual constitution using a schematic or tool that we call “the culture cycle.”

Mapping Mutual Constitution: The Culture Cycle

Figure 1.2 represents culture as a system of four interacting layers that fit together into a dynamic called “the culture cycle” (A. Fiske et al., 1998; Markus & Conner, 2014; Markus & Kitayama, 2010; Markus, 2017b). Culture includes the *ideas*, *institutions*, and *interactions* that guide *individuals’* thoughts, feelings, and actions. This graphic inscribes many of the overlapping ideas of psychology and social psychology’s earliest theorists (e.g., Asch, 1952; Bronfenbrenner, 1979; Bruner, 1990; James, 1890; Lewin, 1948; Mead, 1934; Moscovici, 1988; Wundt, 1916), as well as those of cultural psychology’s early theorists (e.g., Azuma, 1984; Choi, Nisbett, & Norenzayan, 1999; M. Cole, 1996; Cross & Madson, 1997; A. Fiske et al., 1998; Gelfand, Triandis, & Chan, 1996; Greenfield & Cocking, 1994; Heine

& Lehman, 1997; Heine, Lehman, Markus, & Kitayama, 1999; Hong, Morris, Chui, & Benet-Martinez, 2000; Kashima et al., 1995; Luria, 1981; Miller, 1984; Matsumoto, 1990; Mesquita & Frijda, 1992; Miller, 1999; Morris & Peng, 1994; Nisbett, 2003; Nisbett & Cohen, 1996; Oyserman & Markus, 1993; Oyserman, Kimmelmeier, Fryberg, Brosh, & Hart-Johnson, 2003; Rogoff, 1991; Shweder, 1991, 2003; Shweder & LeVine, 1984; Smith & Bond, 1998; Triandis, 1989; Vygotsky, 1978). For example, the depiction of the individual as an embedded part of the culture cycle heeds Bruner's (1990) admonition that it is impossible to "construct a human psychology on the basis of the individual alone" (p. 12). It also incorporates Gelfand and Kashima's (2016) claim that "culture is central to human sociality" (p. iv). Most significantly, with the depiction of interacting layers that influence each other, it represents Shweder's (1991) view of the mutual constitution of culture and psyche that "culture and psyche make each other up" (p. 24).

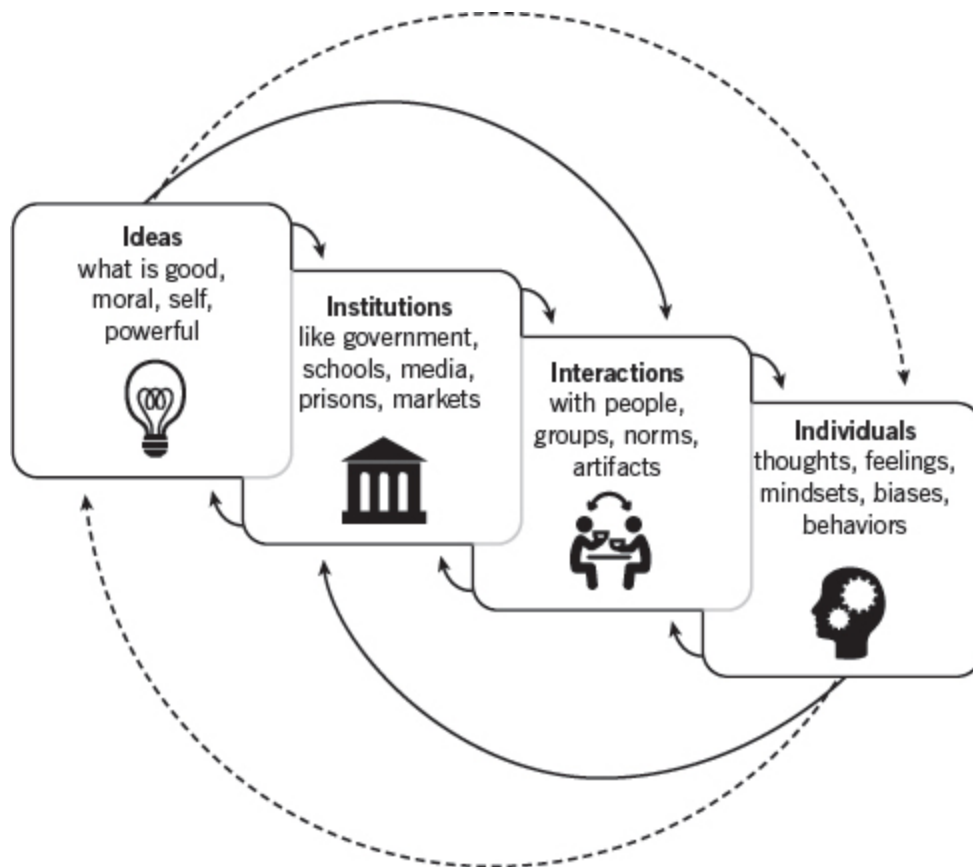

FIGURE 1.2. The culture cycle. Adapted from Fiske, Kitayama, Markus, and Nisbett (1998), Markus and Conner (2014), and Markus and Kitayama (2010).

Analytically, the culture cycle starts from either the left-hand or the right-hand side. From the left, the ideas, institutions, and interactions of an individual's mix of cultures shapes the "I," so that a person thinks, feels, and acts in ways that reflect and perpetuate these cultures. From the right side, I's (i.e., individuals, selves, minds) create (i.e., reinforce, resist, change) cultures to which other people adapt. The "individuals level" is the usual focus of psychologists and includes thoughts, beliefs, attitudes, feelings, emotions, biases, motives, goals, identities, and self-concepts.

The "interactions level" is the part of the culture cycle in which most people live their lives. As people interact with other people and with human-made products (artifacts), their ways of life manifest in everyday situations that follow seldom-spoken norms about the right ways to behave at home, school, work, worship, and play (Gelfand et al., 2011; Kashima, 2014, 2016; Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997; Rogoff, 2016). Guiding these practices are the everyday cultural products—stories, songs, advertisements, social media, tools (e.g., phones, laptops), architecture, and so forth—that make some ways to think, feel, and act easier, more fluid, or better supported by the world a person inhabits than others.

The next layer of culture is made up of the "institutions level," within which everyday interactions take place. Institutions spell out and formalize the roles for a society and include government, religious, legal, economic, educational, and scientific institutions. As an example, economic institutions (e.g., capitalism, socialism), and their associated structures and policies about the distribution of material resources, are particularly significant. For the most part, people are unaware of all the laws and policies at play currently or historically in their cultures. Yet institutions exert a formidable force by providing incentives that foster certain practices and inhibit others (Markus & Conner, 2014; Tankard & Paluck, 2017; Yamagishi & Hashimoto, 2016).

The last and most abstract layer of the culture cycle is the "ideas level," and it is made up of the pervasive, often invisible, historically derived and collectively held ideologies, beliefs, and values about what is good, right, moral, natural, powerful, real, and necessary that inform institutions, interactions, and ultimately, the I's. Because of them, cultures can appear to have overarching themes or patterns that persist, to some extent, across time. To be sure, cultures harbor multiple exceptions to their own

foundational rules and values. But they also contain general patterns that can be detected, studied, and even changed (Markus & Conner, 2014).

Several features of the culture cycle approach are especially relevant to its application: (1) The individual is a part of culture rather than an entity separate from it; (2) all four levels are important in shaping behavior, and none is assumed to be more important or theoretically prior to the others; (3) cultures are always dynamic, never static; all levels continually influence each other, and a change at any one level can produce changes in other levels; (4) the culture cycle includes structures and structural dynamics within the cycle and does not separate the cultural from the structural, and structures go hand in hand with meaning systems that animate them and help them exert their influence; (5) the four layers of the culture cycle may be in alignment and support one another or they may be misaligned and in tension; (6) within individuals, depicted here by a head with a gear, are multiple interlocking physiological and genetic systems; and (7) culture cycles are embedded in ecological systems, and all of the systems—within the individual and without—are coevolving.

Being a Person Is a Cultural Project

The Me in the Middle

What is a psychologist to do with culture cycles? Quadrupling the size of the field—adding interactions, institutions, and ideas to the already overly complex terrain of individuals—can seem daunting at best. The invitation here is not for psychologists also to become sociologists, anthropologists, economists, political scientists, historians, and biologists (although we are not discouraging that!). The goal for psychologists, regardless of their particular process or dependent variable of interest, is to widen their analytical angle as they work to conceptualize, theorize, explain, predict, or change people's behavior.

For the most part, psychologists seek the sources of behavior inside the brain and body of the person. A sociocultural perspective encourages looking at a much wider arc of influences on the individual (e.g., Luria, 1981). As the definitions of culture discussed previously reveal, complex and

continually evolving cultural patterns of all types provide frameworks for agency or for individuals' thinking, feeling, and acting. The anthropologist Clifford Geertz (1973) wrote that an important starting point in understanding behavior is “to figure out what the devil [people] think they are up to” (p. 29). This is the question of agency. Everyone is agentic, but just what they understand themselves to be doing and what motivates them to act can vary dramatically by context (Markus, 2016).

From the perspective of psychology, one of the most important functions of cultures is to provide guidance for what the individual should be doing and how to be a person. As shown in [Figure 1.2](#), what it means to be an individual or a self—that is, how people in different cultures tend to answer life's essential “Who am I?” and “What am I doing/should I be doing?” questions—are among the big ideas that animate culture cycles. A self is the “me” and the “I” at the center of a person's experiences and is the referent for agency. This self mediates and regulates behavior by coordinating and integrating cognitive, affective, and motivational activity (Markus & Nurius, 1986; Markus & Wurf, 1987; Oyserman, 2007, 2015; Oyserman & Markus, 1993). The self also provides a coordinating framework for brain functioning (Han & Humphreys, 2016; Ma et al., 2012; Varnum, Shi, Chen, Qui, & Han, 2014; Zhu, Zhang, Fan, & Han, 2007; see also Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume). Grounded in culture-specific ideas about how to be a normatively appropriate person, the self directs, weaves together, and lends coherence to attention, perceptions, feelings, memories, hopes, fears, expectations, and goals. A self is a repository or system of many selves (also called “identities”), some of which are more chronically active and others of which are cued and activated by the situation. Considering the potential meanings and relevance of any stimulus or task to the “me” is a useful starting point when making sense of individuals' behavior, or for conceptualizing how to redirect or change behavior (Wilson, 2011).

Recent studies provide strong support for the powerful impact of how people construe themselves and their actions (i.e., their implicit theories, mindsets, schemas) on their motivation, performance, and physiology. People who construe their abilities as malleable and capable of cultivation (i.e., who have a growth mindset), for example, perform better than those who construe their abilities as stable and something that they are born with

(i.e., who have a fixed mindset; Dweck, 2006; Yeager et al., 2016). Students who are the first in their families to attend college, and who learn how to construe their working-class backgrounds as a resource for negotiating the world, perform better than those without this lay theory (Stephens, Hamedani, & Destin, 2014). And people who construe their stress as an opportunity for growth outperform, and show more optimal physiological responding, than those who view their stress as deleterious to their health (Crum, Akinola, Martin, & Fath, 2017; Crum, Salovey, & Achor, 2013).

When self-construals are widely shared and inscribed—that is, reflected and promoted across the ideas, institutions, and interactions of various culture cycles—they can be called intersubjective schemas, cultural schemas, cultural models, or social orientations (D’Andrade, 1984; Holland & Quinn, 1987; Lamont, Adler, Park, & Xiang, 2017). These collective mindsets play a significant role in how people understand themselves and one another, and how they coordinate their behavior. They function by providing blueprints for how to think, feel, and act in the world, and often result in different ways of living and being a person, also called “selfways,” “folkways,” or “lifeways” in the literature (Markus, Mullally, & Kitayama, 1997; Rogoff, 2016; Sumner, 1906; Adams, Estrada-Villata & Ordóñez, 2018).

Two Normative Ways of Being a Self: My Way and the Right Way

Among the many different ways people can construe themselves, cultural psychological research provides consistent evidence for at least two shared, influential, and widely practiced types of self-construals or social orientations. In a given situation or across situations, people can perceive and understand themselves to be separate from and *independent from others* or they can perceive and understand themselves as connected to and *interdependent with others* (Markus & Kitayama, 1991, 2010; see [Figure 1.3](#)). How these two construals are realized, and the relative balance between the two in a given culture, can vary dramatically depending on a wide range of contextual factors, including the ecology, historical period, economic system, philosophical and religious orientation, and rate of social change (in this volume, see Keller, [Chapter 15](#); Talhelm & Oishi, [Chapter 4](#); A. Cohen &

Neuberg, [Chapter 32](#)). An independent model of the self is more prominent and normative in the West, whereas an interdependent model of the self is more prominent and normative in non-Western cultures that characterize the majority of the world (Adams, 2005; Gelfand & Kashima, 2016; Henrich, Heine, & Norenzayan, 2010; Kitayama & Cohen, 2007; Markus & Kitayama, 1991, 2003, 2010; Kitayama, Duffy, & Uchida, 2007; see [Figure 1.3](#)).

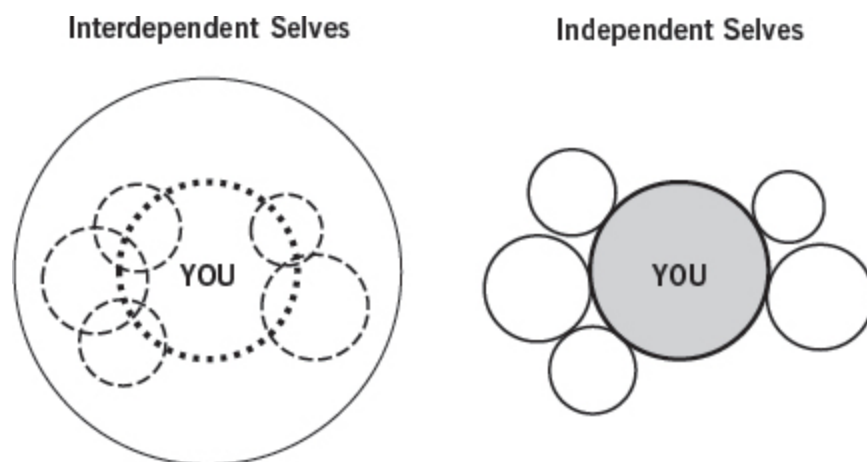

FIGURE 1.3. Interdependent and independent selves. Adapted from Heine (2015), Markus and Conner (2014), and Markus and Kitayama (1991, 2010).

In many Eastern cultural contexts, for example, national and regional culture cycles contain a confluence of multiple historically derived ideas, philosophies, religious institutions, and daily practices that promote a way of being and construal of the self as a connected, relational individual—as *interdependent*. In many Western cultural contexts, in contrast, a different set of national and regional culture cycles promote a way of being and construal of the self as a separate, bounded, autonomous individual—as *independent*. Engaging in culture cycles is the basic, active, and constant process of human life that transforms the biological being into an individual.

With an independent self comes an *independent style of agency* or acting in the world (i.e., “my way” agency). The emphasis is on being a unique, separate individual, expressing the self and influencing others and the world, being free from constraints as well as free to choose, and being equal to others—represented by the shaded area in the independent self in [Figure 1.3](#) (Heine, 2015; Markus & Conner, 2014; Markus & Kitayama, 1991, 2010).

When an independent way of being is guiding behavior, personal preferences, feelings, attitudes, mindsets, individual goals, and feelings about the self (e.g., a sense of control, self-esteem, self-confidence) influence and drive behavior. These internal characteristics have behavioral force; they are the source of agency.

For example, in cultural contexts that emphasize independence, a person's attitudes, feelings, and preferences guide behavior (Riemer et al., 2014). Attitudes toward the environment predict ecologically conscious behavior (Eom, Kim, Sherman, & Ishii, 2016), negative feelings predict poor physical and mental health (Curhan, Sims, et al., 2014b; Kitayama et al., 2015; Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume; Miyamoto et al., 2013; Miyamoto, Yoo, & Wilken, [Chapter 12](#), this volume), and personal preferences motivate which spouses, jobs, and products people choose (Chen, Austin, Miller, & Piercy, 2015; Guan et al., 2015; Savani, Markus, & Conner, 2008; Savani, Morris, & Naidu, 2012; Shavitt, Cho, & Barnes, [Chapter 25](#), this volume). In these contexts, affirming the independent self improves performance (Covarrubias, Hermann, & Fryberg, 2016), and commitment to individual goals maintains motivation (Kizilcec & Cohen, 2017). Focusing on others—more common in interdependent contexts—can actually undermine motivation and performance (Fu & Markus, 2014; Hamedani, Markus, & Fu, 2013). The source of agency from an independent perspective is experienced as coming from *inside* the individual (Plaut & Markus, 2005), and good or normative behavior is self-regulated behavior. In these contexts, *subjectivity* or what an individual personally expects, believes, thinks, feels, and wants, is the primary driver of behavior.

With an interdependent self comes an *interdependent style of agency* or acting in the world (i.e., “the right way” or normatively appropriate agency). Here, the focus is on relationships, referencing and communicating with ingroup others, similarity to others, adjusting to situations, following norms, being rooted in traditions, meeting obligations, and being ranked in hierarchy—represented by the dotted lines in the interdependent self in [Figure 1.3](#) (Kim & Lawrie, [Chapter 10](#), this volume; Heine, 2015; Markus & Conner, 2014; Markus & Kitayama, 1991, 2010; Rai & A. Fiske, 2011). When an interdependent way of being is guiding behavior, relationships, others and their expectations, obligations, duties, roles, responsibilities, and norms (i.e., shared or common sense about how to behave) influence and drive a

person's behavior. Connections and commitments to others, as well as what others think, expect, or require, have behavioral force; they are the source of agency. In situations where there is relatively greater focus on other-regulation as opposed to self-regulation, subjectivity may exert less behavioral force, and individuals can be relieved of some burdens of individual choice and control. The solid line circumscribing the selves and others in the depiction of interdependent selves (See [Figure 1.3](#)) represents a boundary between the ingroup (i.e., those with whom the self is interdependent) and outgroups (i.e., those with whom the self is not considered to be interdependent). This ingroup/outgroup boundary is much less marked and observed in independent contexts that prescribe unconstrained interaction among free and equal individuals.

Recent research also shows that in cultural contexts emphasizing interdependence, emotional experience depends more on others than on the self (Masuda, Gonzalez, Kwan, & Nisbett, 2008; Uchida, Townsend, & Markus, 2009); marriage and employment decisions depend on important others (Chen et al., 2015; Guan et al., 2015; Savani, Markus, Naidu, Kumar, & Berlia, 2010); peer endorsements predict product choices (Savani et al., 2008; Sia et al., 2009); and close and important others motivate behavior (Covarrubias et al., 2016; Lamm et al., 2017; Sims et al., 2018; Stephens, Fryberg, Markus, Johnson, & Covarrubias, 2012; Torelli, Leslie, Stoner & Puente, 2014; Tripathi, Cervone, & Savani, 2018). Furthermore, people accommodate requests, exhibit more patience, and give to others without concern for reciprocity (Miller et al., 2014; Perlow & Weeks, 2002; Savani, Morris, Naidu, Kumar, & Berlia, 2011); have more socially oriented memories (Q. Wang, 2016); attend more to the social context in judging emotions (Masuda et al., 2008, Masuda, Russell, Li, & Lee, [Chapter 8](#), this volume); and give more Facebook likes and fewer status updates (S. Hong & Na, 2017). Further, among people who hold a more interdependent model of self, cross-situational inconsistency is often less predictive of well-being (Church et al., 2014; Cross, Gore, & Morris, 2003; Diener & Suh, 2002), behavior that is inconsistent with personal preferences is more common (Savani, Markus, & Conner, 2008) and does not arouse as much cognitive dissonance (Heine & Lehman, 1997; Hoshino-Browne et al., 2005; Kitayama et al., 2004), and failing to practice what one preaches receives less moral condemnation (Effron, Markus, Jackman, Muramoto, & Muluk, 2018).

The source of agency from an interdependent perspective is experienced as coming from *outside* the individual (Plaut & Markus, 2005; Markus, 2016), and good or normative behavior is very often other-regulated behavior that is responsive to expectations and obligations. In these contexts, “connectivity,” or how a person is related to and linked with others is the primary driver of behavior. Another type of evidence supporting interdependent agency or the significance of others in shaping behavior comes from recent research demonstrating how cultural norms—what other people think, feel, or do in a given context—explains and powers behavior in multiple domains and circumstances (Gelfand et al., 2011; Harrington & Gelfand, 2014; Riemer, Shavitt, Koo, & Markus, 2014). Good or normative behavior is more other-regulated as compared to self-regulated. Agency is thus less locked within the individual, more interpersonal, and relatively objective (i.e., there is more emphasis on what others think and feel; Tsai & Clobert, [Chapter 11](#), this volume).

As the culture cycle approach depicts, differences in agency and its associated psychological tendencies are responses or adaptations to particular sociocultural requirements. These patterns shape how actions can be regulated and whether agency is experienced as primarily internal and self-regulated or as external and other-regulated (Adams, Bruckmüller, & Decker, 2012; Carey & Markus, 2016; Kitayama et al., 1997; Kitayama, Duffy, & Uchida, 2007). Interdependent ways of being, either chronic or activated, are associated with relatively tight connections among people, producing a social order in which cooperation (and sometimes competition) is promoted and protection from threat is assured, but one in which breaking or ending connections is relatively difficult (Carey & Markus, 2017; Kim, Sherman, & Updegraff, 2016; Morris, Hong, Chiu, & Liu, 2015b; Kitayama et al., 2007; Yamagishi & Hashimoto, 2016; Yuki & Schug, 2012). Independent ways of being are more often associated with more material resources and looser connections among people, giving rise to a social landscape in which people have the opportunity to choose according to their preferences (e.g., Adams et al., 2012; Stephens, Markus, & Phillips, 2014), and, in fact, must self-promote and develop internal traits because they are less assured of ingroup protection (Yamagishi & Hashimoto, 2016).

Notably, these two styles of agency can also be activated in individuals by situationally prompting them to construe themselves as either

independent or interdependent in the moment (e.g., Gardner, Gabriel, & Lee, 1999; see also Greenfield, 2009; Heine, 2015; Keller & Bard, 2017; Markus & Conner, 2014; Mesquita, De Leersnyder, & Albert, 2014; Oyserman & Yan, [Chapter 20](#), this volume). The question of whether the “me” is independent or interdependent, that is, operating as an “I” or as a “we” in a given context or situation, seems to be a universal existential theme (Keller & Kärtner, 2013; Shweder & Bourne, 1984) and many people have some experience with both of these styles of agency.

The evidence for these conclusions is robust and growing. Most of it is from comparisons between Western contexts (North American and European cultural contexts) in which an independent style of agency is familiar and practiced, and Eastern contexts (East and South Asian cultural contexts) in which an interdependent style of agency is more familiar and practiced. Researchers have also looked at interdependent agency in Middle Eastern and African contexts (Dzokoto, 2010; Uskul, Cross, Günsoy, & Gul, [Chapter 30](#), this volume; Uskul, Kitayama, & Nisbett, 2008). Recently studies have also examined agency in U.S. working-class and Latinx, Native American, and African American contexts, in which an interdependent style of agency is practiced and familiar (sometimes right alongside an independent style of agency; Brannon, Markus, & Taylor, 2015; Fryberg, Covarrubias, & Burack, 2013; Holloway, Waldrip, & Ickes, 2009; Kraus, Callaghan, & Ondish, [Chapter 27](#), this volume; Ramírez-Esparza, Chung, Sierra-Otero, & Pennebaker, 2012; Stephens, Markus, & Townsend, 2007). Together, these studies are beginning to reveal with more detail and precision some of the sources and mechanisms of interdependent agency.

At least three crosscutting understandings emerge from research on culture and agency. First, interdependent agency does not involve a grudging attention to others, role prescriptions, or norms. Instead, people actively seek to behave so as to be part of relationships or larger wholes, and so attune themselves to situations and patterns of interaction that require this behavior, often effortlessly and without awareness. Second, independent agency also involves conforming to norms and other-regulation; the difference is that the norm is “not to follow the norm” and to do things “my way.” One consequence of independent agency, for laypeople and scientists alike, is that the role of sociocultural norms becomes hard to track and often seems to disappear altogether. Third, given psychology’s near exclusive

emphasis on independent agency, many everyday forms of interdependent agency have yet to be examined as sources of agency themselves. With the exception of research on honor (i.e., one's reputation in the eyes of others; Cross et al., 2014; Leung & Cohen, 2011; Nisbett & Cohen, 1996; Uskul et al., [Chapter 30](#), this volume), they include loyalty, solidarity, obligation, duty, sacrifice, hierarchy (vs. equality), roles, responsibilities, other-regulation (vs. self-regulation), and normative- or authority-driven behavior (Markus, 2016).

WHAT CULTURAL PSYCHOLOGISTS KNOW ABOUT PERSONS AND CULTURES

In the decade since the publication of the first *Handbook of Cultural Psychology* (Kitayama & Cohen, 2007), thousands of studies in all areas of psychology have examined the ways in which culture shapes behavior. Across these studies, in multiple cultural contexts with an array of methods, several crosscutting, high-level generalizations are emerging about people and about cultures. Before reviewing a selection of recent findings and theories in more detail, we describe five of these generalizations in the following sections: (1) people are different—some are WEIRD, but most are not; (2) cultures “R” us, not overlays or lenses; (3) everyone is multicultural and intersectional—it's complicated; (4) some cultures are more equal than others—how difference becomes inferiority; and (5) it's cultural—of fits and clashes.

People Are Different—Some Are WEIRD, but Most Are Not

One of the field's major achievements has been to raise awareness among psychologists that most existing scholarship is based on studies of middle-class people in the West, carried out by middle-class researchers in the West. Arnett (2008) argued that we have focused far too narrowly on U.S. Americans, who only comprise about 5% of the world's population, and have neglected the other 95%. Given this research bias, he asks whether

psychology can truly consider itself to be a science of *human* behavior. He notes that most people in the world live in strenuous, under-resourced circumstances, and that the main social unit in these contexts is large, multigenerational families that promote interdependence, obligation, and mutual support. As a consequence, many psychological findings and generalizations from the middle-class West are likely to be a poor fit at best for most of the world's people (see also Brady, Fryberg, & Shoda, 2018; Greenfield, 2017; Greenfield et al., 2006; Miller, 1999; Rogoff, 2003).

The economist–social psychologist team of Henrich, Heine, and Norenzayan ratcheted up the significance of this problem with the observation that the 15% of the world's population that psychology understands best, is, in fact, WEIRD: an acronym that stands for Western, Educated, Industrialized, Rich, and Democratic (Henrich et al., 2010). Moreover, WEIRD is not just an acronym. The West is actually historically, economically, and geographically odd compared to much of the world's population. This means that the relatively well-resourced culture cycles of the middle-class West that shape people with independent selves and an independent style of agency operate with very different ideas, institutions, and interactions.

These WEIRD culture cycles are saturated with ideas about the natural rights of free and equal individuals, institutions like the legal system that support and formalize these ideas, and interactions are organized by social networks built around single-generation families with few children. In these WEIRD culture cycles, people spend more time alone and are encouraged to focus on themselves, making choices based on their preferences, expressing their emotions and opinions, following their own unique paths, and charting their futures. These are the so called “basic” humans that psychologists know best. Perhaps the most significant contribution of cultural psychology's comparative approach in the last decade has been to shine a bright light on middle-class, Western cultural contexts and to see them as particular ways of living that give rise to particular ways of being. Many phenomena and processes long considered to be the result of the unfolding of universal human nature may now be examined for the ways in which they are actually culturally constructed and maintained. Qi Wang (2016) advises that incorporating cultural psychology into research

programs is feasible and necessary, and that *all* psychologists should be *cultural* psychologists.

Cultures “R” Us, Not Overlays or Lenses

More than two decades ago, Shweder and colleagues (1997), in a chapter with the subtitle “One Mind, Many Mentalities,” wrote “that the wager of cultural psychology is that relatively few components of the human mental equipment are so inherent, hard wired, or fundamental that their developmental pathway is fixed in advance and cannot be altered through cultural participation” (p. 867). That wager has paid off. Participating in communities and engaging with particular sets of ideas, frames, schemas, or mindsets can alter how and what people see, desire, feel, think, and act; how they learn and how they perform; and even how they respond physiologically (Kitayama et al., [Chapter 3](#), this volume). Revealing when, why, how, and to what extent it happens is now the charge of cultural psychology.

The empirical examples in [Figure 1.1](#) shine a bright light on what a careful consideration and interrogation of cultural ideas and practices can contribute to our understanding of human psychological functioning, as well as the many challenges and research opportunities that are ahead for a socioculturally grounded psychology. In Lamm and colleagues’ (2017) study, children are given Walter Mischel’s classic “marshmallow test,” in which an adult tells a child that if she does not eat the marshmallow in front of the adult right now, she may have a second one if she waits until an adult comes back into the room. Many Western lay observers and psychologists alike assume that 4-year-olds facing the prospect of a delicious treat (a marshmallow in the Global North or an equally appealing alternative sweet in the Global South) will “naturally” struggle to fight their desire and the temptation of consuming it immediately.

In reality, an independent model of agency underlies the assumption that people are driven to express their individual needs and preferences and can suffer negative consequences if constrained from doing so. Waiting is the opposite of freely exercising one’s own preferences—thus, the struggle of whether to eat the marshmallow immediately or wait and postpone

gratification to obtain a second treat. Some German children manage to resist. To distract themselves, they move, twist, whine, hum, and make desperate, unhappy faces. Nearly twice as many Nso children in rural Cameroon, on the other hand, wait for the second treat. As these children supposedly “resist” the temptation to eat the first marshmallow, they do not manifest the same signs of “struggle” as the German children do.

Cameroonian and German culture cycles provide insights into why these children behaved differently. In Cameroon, one prevalent cultural idea is that an individual is a part of an encompassing social whole, and the overarching goal that guides a person’s behavior is to figure out how to fit within this whole and adjust to it. As interdependent agents with interdependent selves, people live in intergenerational extended families and are used to adjusting to others. At the interactions level of the culture cycle, parenting practices emphasize awareness of one’s place in the social hierarchy and respecting elders. In contrast, German culture cycles foster independent agency and an independent self. Parenting practices instead stress developing personal interests and expressing individual preferences and emotions. When one compares these two culture cycles and their underlying models of agency, one can see that the appeal of a sweet may be universal, but the behavioral course and outcome of this appeal is quite different.

This fascinating study opens the door to many lines of inquiry. Will the children who can delay gratification show more achievement in later life as they do in the United States (Mischel, 2014)? Do children in Germany and Cameroon experience the situation similarly? If not, what do they experience and why? How do parents structure interactions to foster these different styles of regulation and associated ways of being? Is it the case that the Nso children reveal no negative affect, or do they learn effective strategies of down-regulation? For example, analyzing East Asian contexts, Tsai and colleagues propose that calm affect is highly functional, in that it allows people to attend to and adjust to others, which is useful for interdependent selves and agents (Tsai, 2017; Tsai, Knutson, & Fung, 2006). How are such differences in arousal socialized and maintained (Tsai & Clobert, [Chapter 11](#), this volume)? What does variability in arousal or other aspects of emotional experience (e.g., degree of embodiment, social sharing of emotion, emotional practices) mean for the conceptualization of “basic”

human emotions (Mesquita & Barrett, 2017)? What are productive and innovative methods for answering these types of questions?

Psychology is the science of the minds, brains, and behavior of individuals, but what the evidence now underscores is that these minds, brains, and individuals are always in situations and cultures, and are responsive to them. The strong implication is (1) that minds, brains, people, and their situations are best conceptualized and theorized together, and (2) that minds, brains, and people are more malleable and flexible than psychologists have previously realized. Patterns of activity that are observed in behavior and in the brain are made up of, and are made up by, the sociocultural. The sociocultural, then, is not an overlay on the basic that can be peeled back to reveal the underlying “really real.”

Psychology’s focus on people in WEIRD cultural contexts has led to an essentialist perspective that focuses on people’s internality, locates the sources of action inside the person, and conceptualizes psychological functioning as basic and discrete psychological processes (e.g., attention, perception, cognition, emotion, motivation). A cultural perspective may eventually lead to a psychology that instead focuses more on shared and contextualized human activities (Rozin, 2001), including eating (Rozin, Ruby, & Cohen, [Chapter 17](#), this volume), attachment (Keller, 2016; Keller, [Chapter 15](#), this volume), learning (Rogoff, 2016), working (Levine, Harrington, & Uhlmann, [Chapter 23](#), this volume), relating (Kim & Lawrie, [Chapter 10](#), this volume), communicating (Keller, [Chapter 15](#), this volume), consuming (Shavitt, Cho, & Barnes, [Chapter 25](#), this volume), being well (Miyamoto, Yoo, & Wilken, [Chapter 12](#), this volume), fitting in and acculturating (Mesquita, De Leersnyder, & Jasini, [Chapter 19](#), and Morris, Fincher, & Savani, [Chapter 18](#), this volume), and more, most of which have connecting or relating to others and the social world as key features (Adams, Estrada-Villata, & Kurtis, 2018).

Everyone Is Multicultural and Intersectional—It’s Complicated

Navigating the norms and demands of two or more nations, regions, races, or ethnic groups—many of them at odds with one another—is a formidable

challenge for people across the globe (Benet-Martínez & Hong, 2014; Leung & Koh, [Chapter 21](#), and Mesquita et al., [Chapter 19](#), this volume). As people encounter each other in bedrooms, classrooms, courtrooms, and boardrooms, it is important that they recognize and reject what Morris and colleagues call culturalism: “a categorical conception in which individuals are shaped by one primary culture and the world’s cultural traditions are separate and independent” (Morris et al., 2015a, p. 633). As popular and scientific attention focuses on culture beyond nations or regions, and the scope of cultural analysis expands to consider the many cultures of people’s lives, it may become easier to fight culturalism and see the fact that people are all multicultural in one way or another. All people participate in many culture cycles simultaneously, and all lives contain a variety of cultural intersections (A. Cohen, 2009; A. Cohen & Varnum, 2016; Markus & Conner, 2014). As a sociocultural perspective grows in prominence, it may become more obvious and possibly easier to reject color blindness, an ideology that claims that culture, race, ethnicity, as well as gender and other significant social distinctions, should not be major factors that shape the experiences and outcomes of people’s lives. Currently, color blindness is still a powerful ideology in places such as the United States, bringing with it neglect or even denial of the fact that social categorizations fundamentally organize society and have life-altering consequences (e.g., Markus & Moya, 2010; Omi & Winant, 1986/2015; Plaut, 2010).

From a cultural psychological perspective, people can be characterized as nodes in multiple intersecting, open, and constantly shifting culture cycles. As an example, many people in U.S. national contexts are often goal-directed, focused on self-promotion and expressiveness, and have a sense of self that is highly independent compared to people in East Asian national contexts. Yet, as U.S. national culture cycles intersect with U.S. social class culture cycles, the characterization of U.S. psychological tendencies may change markedly. In contexts characterized by fewer economic resources, less status, and lower societal rank, people need to depend on, rely on, and fit in with others who can help buffer the constraints of riskier worlds (S. Fiske & Markus, 2012; Markus & Stephens, 2017; Kraus, Callaghan, & Ondish, [Chapter 27](#), this volume). As they participate in smaller, tighter social networks with scarcer resources, working-class U.S. Americans are more likely to emphasize cooperation and protection from threat, have more

contextual/holistic ways of understanding the world, and focus on referencing others, maintaining ties, and adjusting to others compared to middle-class Americans. While middle-class and working-class culture cycles in the United States are both likely to foster independence and the importance of hard work and personal responsibility through shared American ideas and institutions (Carey & Markus, 2016; Stephens, Markus & Phillips, 2014), their culture cycles can diverge markedly at the level of everyday interactions and their interrelated individual psychological tendencies (Markus, 2017). In contrast, middle- and upper-class U.S. individuals have the often unseen advantage of having access to more material and social resources to realize prevalent cultural mandates like those reflected in the American Dream.

As Japanese national culture cycles intersect with Japanese social class culture cycles, the outcomes are both similar and different than the U.S. case. Miyamoto and colleagues (2018) found that in Japan, higher SES is associated with higher self-oriented psychological traits and socialization values, as they are in the United States. Yet, notably, this self-orientation does not come at the expense of other orientation. Higher SES is also associated with higher other-oriented psychological traits and socialization values. In Japan, it is those in higher SES contexts who face the multitasking challenge of pursuing their own goals while also fulfilling the social responsibilities that are foundational to competent personhood in Japanese and other East Asian culture cycles.

One of the obvious challenges of multicultural, intersectional selves is that of concatenating complexity. Theoretically, all significant social categories are meaningful and can powerfully shape psychological experience, but what is one to do in the analytic moment? Addressing this “All of us are multicultural” point, Markus and Conner (2014) analyzed eight cultural divides that have been reasonably well studied in the social sciences, and that have been shown to be consequential for people’s answers to the universal “Who am I/who are we” questions of identity and belonging: East versus West, Global North versus Global South, men versus women, rich versus poor, whites versus people of color, businesses versus governments and nonprofits, liberal versus conservative religious groups, and coasts versus heartlands. They show that one set of culture cycles (i.e., those of the West, the Global North, men, the rich or middle-class, whites,

businesses, liberal religious groups, and the coasts), tend to promote independence, while the culture cycles of the less well-resourced and less powerful sides of these divides tend to promote interdependence. Markus and Conner propose that any given person's social orientation toward independence or interdependence will depend on that person's mix of these culture cycles and on which ones are salient at a given time or situation. Given the hegemony of independence in American ideas and institutions, along with the historical dominance of color blindness, the interdependent tendencies that arise from intersections of national culture with social class, race and ethnicity, and gender may go unrecognized and are often misunderstood and stigmatized.

The most well-developed theorizing on intersectionality focuses on the interplay of race and gender identities. It proposes that the many factors that contribute to one's identity should not be considered separately, but instead, simultaneously and as interacting to influence one's privilege and treatment in society (E. Cole, 2009; Crenshaw, 1989; Goff & Kahn, 2013; E. Hall, Galinsky, & Phillips, 2015; Settles & Buchanan, 2014). These researchers have been most concerned with the power and social justice implications of intersectionality, especially in law, the workplace, and education. Researchers studying multiculturalism in cultural psychology have instead focused primarily on the psychological experience of having multiple identities and their behavioral consequences (Benet-Martinez & Hong, 2014). These two literatures are highly relevant for each other but have yet to intersect.

Some Cultures Are More Equal Than Others—How Difference Becomes Inferiority

In the course of expanding the scope of cultural comparison and revealing different and previously unexamined ways of living and ways of being, one fact is in high relief. Some cultures are more equal than others. There is a clear power hierarchy among cultures. One project of cultural psychology is to compare cultures' different ways of living and being, and to test the hypothesis that there is more than one good and viable way of living and being (e.g., what looks like conformity and a failure to express oneself from

a Western perspective is adjusting in the service of group harmony from an Eastern perspective; Kim & Markus, 1999). This task is challenging enough. Yet dramatically complicating the cultural comparison process is that, across most cultural divides, the cultures being compared should not be arrayed horizontally, side by side, but rather vertically, because one has more material resources, power, and status than the other (e.g., the Global North vs. the Global South, the middle class vs. the working class, men vs. women, whites vs. African Americans).

It is easy to fall into the trap of culturalism (Morris et al., 2015a) and assume that the cultures on either side of a divide are separate from each other, and that their cultural patterns reflect only their own valued, self-sustaining ideas and practices. This way of conceptualizing culture ignores the fact that the observed cultural patterns of the less powerful group are, in some significant part, a function of contending with the imposition of the more powerful culture's ideas and practices (Markus, 2008). When what the less powerful group does is shown to be less efficient, competent, or healthy (often according to the metrics and measurement instruments devised by the more powerful group), the assumption may be that the less powerful group is different because its members' ways of living and being are somehow inferior or faulty (Moya & Markus, 2010). Further, these power and resource differences among cultures have real and significant consequences, and serve to maintain the dominance of the more powerful group. (See, for example, the recent headline-grabbing fight over whether women in Silicon Valley are biologically or culturally unfit to be coders and engineers as a way to explain their dramatic underrepresentation in these careers.) As such, cultural differences come to be constructed not simply as differences, but as indications of the "inferiority" of the less powerful group (Adams & Estrada-Villalta, 2017, Croizet, 2012).

The task for cultural psychologists, then, is to consider not only the mutual constitution of culture and psyche, but also what is more properly called "downward constitution": the experience of being in a setting in which "one is exposed to a potentially limiting and devaluing concert of representations, historical narratives, possible judgments, treatments, interactions, expectations, and affective reactions" (Thomas, 1992, as paraphrased in Markus, Steele, & Steele, 2000, p. 235). Some of the observed practices and tendencies of a given sociocultural context under study are

claimed and valued by participants in that context, while others may be imposed and unclaimed and thus resisted and challenged. Observed psychological tendencies can reflect adaptation to one, both, or a blend of incorporation or resistance. The analysis of how cultures and psyches make each other up also requires an understanding and an explanation of downward social constitution within its cycles (see Figure 1.4 for an example of the downward constitution of African Americans in the U.S.).

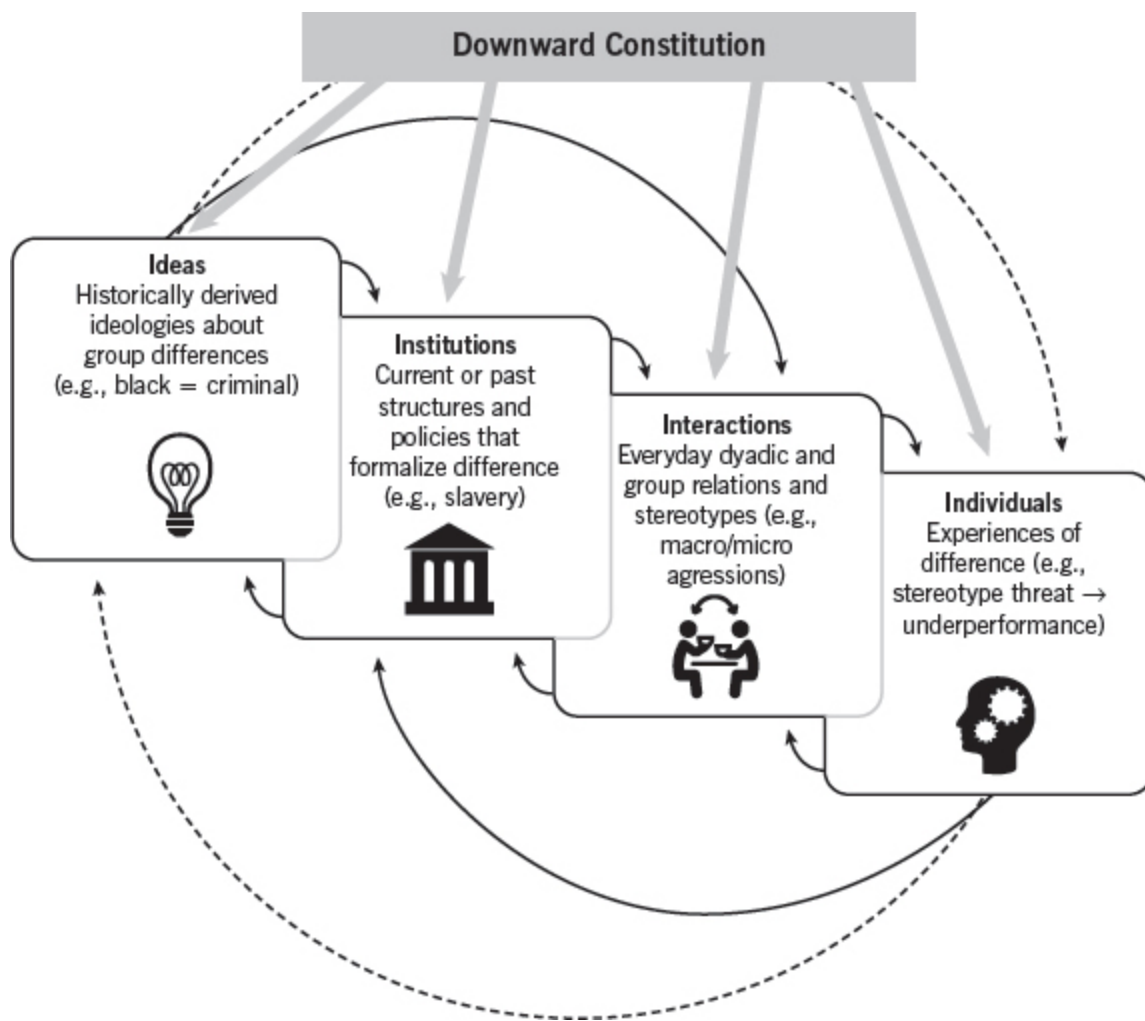

FIGURE 1.4. Downward constitution.

A cultural analysis that incorporates downward constitution should include an awareness of (1) historically derived *ideas* about group differences (e.g., black = criminal, Latinx = illegal); (2) the role of current or

past *institutions* in how policies and structures formalize difference, as well as inscribe and maintain a particular social ordering (e.g., slavery, immigration policy); (3) the role of *interactions* in perpetuating norms that guide behavior (e.g., who plays with whom, who dates whom), the actions of other people (e.g., being followed in a department store, being handcuffed without cause during a traffic stop by the police), and the expectations of others (e.g., employers' and teachers' views about who is smart and capable or who is likely to be a troublemaker in the classroom or on the street); and (4) at the level of *individuals*, people's experiences of difference (e.g., stereotype threat, invisibility).

Attending to the dynamics of downward constitution in a cultural analysis importantly directs our attention to the negative, essentializing, and deficiency-focused ideas and actions that powerful groups in society impose on a less powerful groups. Higher ranking groups, compared to lower ranking groups, often adopt more fixed or essentializing beliefs about the sources of identity and behavior of other groups as a way of maintaining their status (Mahalingam, 2003; Moya & Henrich, 2016). A sociocultural approach offers psychologists a view to the historically derived and context-specific processes by which difference becomes inferiority—a view that is hidden by a focus on the individual level alone (Markus & Moya, 2010; for specific examples, see Adams, Estrada-Villalta, & Ordóñez (2018) for a discussion of how the colonial Global North downwardly constitutes the formerly colonized Global South with various forms of so-called cultural “pathologies”; see Shafir (2017) for a discussion of how people in high SES contexts are disdainful of people in low SES contexts and downwardly constitute them through attributions of inferiority, and Goudeau and Croizet (2017) for a discussion of how certain classroom practices such as hand raising advantage middle-class students while disadvantaging working-class students and often go unseen).

It's Cultural—of Fits and Clashes

As societies and the social sciences have grown more diverse in recent years, there has been a corresponding growth in the volume of research on culture clashes or divides. These clashes occur when a person's understanding or

way of being in the situation does not match or fit with the ideas and practices that are prevalent in that situation. This can happen when, for instance, a student or an employee feels like she is met with a concert of ideas and practices—large and small—in which she is invisible or rendered as potentially inferior (e.g., Brannon et al., 2015; Fryberg & Townsend, 2008; Lewis & Sekaquaptewa, 2016; Purdie-Vaughns & Eibach, 2008; C. Steele, 2010; Walton, Murphy, & Ryan, 2015). One example is when a Latinx lawyer, in the midst of a firm reception or party, is asked, “Where are the drinks?” by a colleague who mistakes her for a server. It can also happen when a familiar and well-practiced way of being (e.g., interdependent agency) meets a set of interactional patterns or institutional policies that have been set up with another way of being in mind (e.g., independent agency; Bencharit et al., 2018; Markus & Conner, 2014; Stephens, Hamedani, Markus, Bergsieker, & Eloul, 2009; Stephens, Townsend, Markus, & Phillips, 2012). One example is when an East Asian middle manager, during performance review time, is told that he does not have the executive presence to move to the C-suites.

The result in both instances is a culture clash or a lack of fit and a sense of dis-ease, difficulty, or discomfort in the person in the clashing or ill-fitting situation. This experience often manifests as a drag on trust, motivation, performance, social interactions, well-being, and even physical health (Fryberg & Martínez, 2014; C. Steele, 2010). Recent examples of the effects of culture clashes include underrepresented or minoritized students in colleges or universities (Yeager et al., 2016), first-generation college students entering institutions of higher education (Harackiewicz et al., 2014; Goudeau & Croizet, 2017; Stephens, Townsend, et al., 2012), immigrants from collectivist societies entering more individualist ones (Cheung, Chudek, & Heine, 2011; De Leersnyder, Mesquita, & Kim, 2011; Sam & Berry, 2010), and women entering male-dominated science, technology, engineering, and mathematics (STEM) fields (Cheryan, Ziegler, Montoya, & Jiant, 2017; Stout, Dasgupta, Hunsinger, & McManus, 2011).

While a culture clash undermines many aspects of behavior, a cultural fit, on the other hand, supports it. Most generally, a fit occurs when one’s way of being (i.e., thinking, feeling, behaving) matches or is congruent with the ways that are common and valued in a given context. For example, U.S. Americans who are independent and fit mainstream U.S. cultural norms and Japanese who are interdependent and fit mainstream Japanese cultural

norms experience better health outcomes (Levine, Miyamoto, et al., 2016b; Levine, Atkins, Waldfogel, & Chen, 2016a). A culture cycle approach is useful to analyze how to intervene to reduce culture clashes and enhance cultural fit. Some well-researched approaches include creating identity-safe classrooms through the incorporation of multiple cues that signal inclusion (Steele & Cohn-Vargas, 2013), and through buttressing students' sense of belonging by framing adversity as common and transient (Walton & Cohen, 2011).

RECENT EMPIRICAL INSIGHTS AND ADVANCES

Psychologists from all areas of the discipline are beginning to take a sociocultural perspective on their research. Even without the explicit comparison of two or more groups, this perspective can change the questions psychologists ask and the ways they seek to answer them. Both *what* cultural psychology scholars are studying today, as well as *how* they are studying it, reflects a maturing of the field and increasing level of analytical sophistication. Here, we give a targeted overview of cultural scientists' key insights in the decade since the inaugural publication of this volume. These advances demonstrate how the psychological is changing how we think about culture, and how we think about culture is changing how we think about the psychological. They also provide the latest empirical evidence for the cross-cutting generalizations discussed previously: that we are not all WEIRD, that ways of being can take multiple forms, and that cultural fit matters.

Going Deep: Genetics and the Brain

Culture shapes not only psychological processes themselves but also the genetic and neural processes that can underlie what we call "the psychological." Culture is not just the ubiquitous water in which we swim; it also operates under the skin, interacting with our genes and brains at the biological level.

As Kitayama and Uskul (2011) importantly underscore, due to the ways the biological and social sciences were used and abused in the past to justify so-called “scientific” racism, it was considered taboo for some time even to breach the topic of cultural differences mapping onto the physical body in any way. As the science behind gene–environment interaction has grown more sophisticated in recent years, however, the data simply do not show that there is any kind of biologically deterministic relationship between genes and cultures. Instead, what scientists have observed is an intricate and flexible process of social and environmental interaction and adaptation that does not affect the genetic code itself, but instead affects how some genes are expressed under certain conditions. Culture, therefore, may influence genetics in a subtle way (in this volume, see Kim & Lawrie, [Chapter 10](#); Kitayama et al., [Chapter 3](#))—it does not change the basic design of the mind or body itself, but rather specific aspects of psychological or behavioral adaptation to particular environmental factors (Kitayama & Uskul, 2011).

How does this take place? Genes and cultures can influence one another both at the macro-level, through what is called gene–culture coevolution, and at the micro-level, through what is called gene–culture interactions (Henrich, 2015; Kim & Sasaki, 2014; Moya & Henrich, 2016; see also Mesoudi, [Chapter 5](#), this volume). Gene–culture coevolution means that cultural ideas, values, and practices have evolved over time and are adaptive, influence the social and physical environments in which people live, and happen in tandem with the genetic natural selection process. As such, certain genotypes may correspond to particular cultural tendencies or reflect different tendencies in different cultural environments. Gene–culture interactions, on the other hand, mean that culture may interact with people’s genetic predispositions to influence how they think, feel, and act, or influence how sensitive particular people are to certain kinds of cultural or environmental experiences (Kim & Sasaki, 2014; Kitayama, King, Hsu, Liberzon, & Yoon, 2016).

What do these interactive processes actually look like? Kitayama and colleagues (2016) recently proposed, for example, that some people may be more genetically sensitive to cultural norms than others, which could help account for individual differences in psychological tendencies within cultural groups. In a study testing this theory, they found that people who carried dopamine receptor gene (*DRD4*) polymorphisms linked to increased

dopamine signaling (7- or 2-repeat alleles) were more likely to exhibit culturally dominant social orientations (Kitayama et al., 2014). That is, American-born European Americans with this gene expression were likely to be more independent than their counterparts without the gene expression. Similarly, Asian-born Asians with the same gene expression were likely to be more interdependent than their fellow Asians without the gene expression. This evidence suggests that the *DRD4* could play an important role in cultural learning, accounting for at least some variation in how people acquire, embody, and enact pervasive social norms. It may help explain, for example, why some of us might seem more like prototypical members of our cultures, while others may be more likely to seem like iconoclasts or rebels who more often go against the grain.

Culture also shapes the mind through how people's brains work, both functionally and structurally (Chiao, 2009; Kim & Sasaki, 2014; Kitayama & Uskul, 2011; see also Kitayama et al., [Chapter 3](#), this volume). Early studies in cultural neuroscience, using brain imaging methods such as functional magnetic resonance imaging (fMRI) and event-related potential (ERP), indicated that there are neural correlates to cultural differences typically captured through self-report and behavioral measures. For example, both Chinese and North American college students showed greater MPFC (medial prefrontal cortex) activation when making judgments about themselves compared to others, consistent with prior behavioral research showing differences between East Asians and North Americans in self-other judgments (Zhu et al., 2007). However, only Chinese participants also showed activation in the MPFC when thinking about their mothers, a close other who is likely interdependent with the self. Indeed, as numerous studies have shown, self-construal has been found to be a consistent mediator of cultural differences in brain activity in explaining differences across both national and religious cultures (Han & Humphreys, 2016; Sasaki & Kim, 2011).

Other researchers have examined the effects of cultural priming on brain activity and have studied the neural correlates of cultural differences in cognitive styles, emotion regulation, and social cognition (in this volume, see Masuda, Russell, Li, & Lee, [Chapter 8](#); Tsai & Clobert, [Chapter 11](#)). Using fMRI to study cultural differences in holistic versus analytic processing styles, for instance, showed that East Asians and European

Americans had to control their attention more when they were asked to adopt the “culturally opposite” processing style when making visual judgments. East Asians exerted greater mental effort (i.e., showed greater frontal and parietal activation) when asked to ignore the context (which contrasts with a holistic processing style), while European Americans showed greater mental effort when asked to pay attention to the context (which contrasts with an analytic processing style; Hedden, Ketay, Aron, Markus, & Gabrieli, 2008). In a study using functional near-infrared spectroscopy (fNIRS), Murata, Park, Kovelman, Hu, and Kitayama (2015) found similar results using a different method to look at brain activity. As for brain structure itself, early research using MRI has shown that some meaningful cultural differences may also develop in the brain’s anatomy, possibly due to the acquisition of different cognitive styles, languages, or self-regulation processes (Sasaki & Kim, 2011; Kitayama et al., 2015). Taken together, this work suggests that the brain is plastic and flexible, responsive to a diversity of cultural inputs and variation.

Spanning Basic Processes: Cognition, Emotion, and Motivation

As showcased in [Figure 1.1](#), culture in all forms shapes the basic psychological processes of cognition, emotion, and motivation. Culture facilitates different styles of thinking, feeling, and acting that guide how people understand themselves and others, as well as how they perceive and navigate the world around them.

Cognition

In addition to continuing to document the effects of analytic–holistic cognitive styles and independent–interdependent social orientations on perception, attention, categorization, and reasoning (see Masuda et al., [Chapter 8](#), this volume), researchers are now analyzing how these cultural differences in cognition originate and develop. Some have hypothesized that adapting to different environmental ecologies, in particular, can lead to

cultural variation in cognition (see also Talhelm & Oishi, [Chapter 4](#), this volume). As an example, to test whether environments that call for greater social interdependence lead to a more holistic cognitive style, Uskul and colleagues (2008) studied three communities in Turkey's Black Sea region that have different ecological environments and local economies. These Turkish communities share a common nationality, language, ethnicity, and geographic region, but differ in how socially interdependent they are.

This variation in social interdependence, Uskul and colleagues (2008) proposed, is due to the fact that these communities have been historically dependent on different kinds of occupations: farming, fishing, or herding. Farming and fishing, on the one hand, require high levels of social cohesion, group collaboration, and staying in one place (i.e., a lot of social interdependence). Herding, on the other hand, requires high levels of autonomy, individual decision making, and moving around to multiple places (i.e., a lot of social independence). They found that farmers and fishers, communities with greater social interdependence, thought more holistically, while herders, a community with greater social independence, thought more analytically. Talhelm and colleagues (2014) found complementary results when contrasting the effects of rice versus wheat agricultural legacies in China, with rice farming requiring much more social cohesion than wheat farming. In support of this hypothesis, they found that people from rice-growing, Southern provinces in China were more likely to be interdependent, holistic thinkers than people from wheat-growing, Northern provinces.

Psychologists have also started to take a more detailed look at when cultural differences in cognition emerge developmentally (see Masuda et al., [Chapter 8](#), and Keller, [Chapter 15](#), this volume). In one study that examined children's artwork, Senzaki, Masuda, and Nand (2014) found that Japanese and Canadian children produced similar landscape drawings (i.e., a drawing of a house and its surrounding environment) and understood the concept of a "horizon" in grade 1. However, by grade 2, cultural differences began to emerge. Japanese children in grade 2 drew the horizon significantly higher up in their pictures, and drew more objects in them overall, than Canadian children of the same age, mimicking a more holistic versus analytic style of visual representation prevalent in Japanese culture and aesthetics. In another study, researchers found that Japanese children's tendency to pay attention to

the context—a common feature of a holistic cognitive style, called “context sensitivity”—increased by age, emerging by 6–7 years of age and reaching adult levels by 8–9 years of age (Imada, Carlson, & Itakura, 2013).

Emotion

Turning from cognition to emotion, researchers are continuing to study how people do emotion differently in multiple cultural contexts, and are now also looking at how emotional norms impact mental health and well-being, how emotions influence the ways in which people acculturate to new cultural contexts, and how emotional norms and biases play out in institutional contexts such as doctors’ offices, schools, and workplaces. Over the past decade, scholars have also been expanding their work beyond East–West cultural comparisons, studying other kinds of cultural contexts, as well as identity intersections within national contexts (Mesquita, Boiger, & De Leersnyder, 2016; in this volume, see also Tsai & Colbert, [Chapter 11](#); Mesquita, De Leersnyder, & Jasini, [Chapter 19](#)).

Culture and emotion researchers, for example, have weighed in on the long-standing assumption that suppressing one’s emotions is pernicious and can lead to negative mental and physical health outcomes. For example, Soto, Perez, Kim, Lee, and Minnick (2011) asked whether this should be the case in East Asian cultural contexts, in which showing emotional restraint is valued over freely expressing one’s emotions. By comparing U.S. European American and Hong Kong Chinese college students’ use of emotional suppression, life satisfaction, and mood, they found that suppression was related to negative psychological functioning (i.e., lower life satisfaction and depressed mood) for U.S. European American students but not for Hong Kong Chinese students. Since expressing one’s emotions is part of being true to oneself in individualistic, independent U.S. culture, it follows that going against this emotional norm by regulating or suppressing one’s emotions is experienced negatively by Americans. Since this emotional logic is not the norm in East Asian contexts, regulating or suppressing emotion is far less likely to result in this kind of negative experience. Instead, in East Asian contexts, negative feelings are an expected part of life, and control over emotional expressions that could disrupt important relations is highly

valued and practiced (Curhan, Sims, et al., 2014b; Kitayama & Park, 2017; Miyamoto et al., 2013). These differences in emotional norms and how they are reflected and promoted in their respective culture cycles can explain why negative feelings are strong predictors of poor health in the United States but not in East Asian contexts.

The power of emotional norms is also evident when people move to a new cultural context. Recent research on emotion and acculturation (see Mesquita et al., [Chapter 19](#), this volume) shows that the extent to which a person's emotional alignment or misalignment with a new culture can matter for transition and adjustment experiences, as well as general mental health and well-being. For instance, Consedine, Chentsova-Dutton, and Krivoshekova (2014) found that immigrant women from diverse places such as the Caribbean and Eastern Europe experienced worse health and well-being the less they fit U.S. emotional norms. They also found that the longer amount of time that these immigrant women spent in the United States, the more they came to fit mainstream American emotional norms. Likewise, De Leersnyder et al. (2011) found evidence of what they call "emotional acculturation"; that is, the more that Korean and Turkish immigrants to the United States were exposed to mainstream U.S. culture, and the more that they engaged in relationships with Americans, the more their emotions fit American norms.

Cultural differences in emotional norms also play out in important ways in institutional contexts and may be a significant but often unseen factor in bias. For example, Tsai and colleagues have explored how mismatches in people's "ideal affect," or how they would ideally like to feel, can play a role in whether people from different cultural groups communicate well with their doctors, think employees or leaders are successful, or see students as smart and engaged in school (e.g., Sims et al., 2018; Bencharit et al., 2018; see also Tsai & Clobert, [Chapter 11](#), this volume). In one study, Tsai and colleagues (2016) found that top-ranked leaders in the United States expressed excitement by smiling big, toothy, "Julia Roberts" smiles in their official photos, while leaders in China expressed calm by smiling more modest, closed-mouth, "Mona Lisa" smiles in their official photos. These leaders' emotional expressions reflected differences in ideal affect in each culture: U.S. culture values excitement and high-arousal, positive emotions, while Chinese culture values calm and low-arousal, positive emotions (Tsai

et al., 2006). These cultural differences in ideal affect may also contribute to bias when cultural mismatches arise. For example, Asian Americans in the United States are often stereotyped as being “too passive” to be strong leaders or “too quiet” to be the smartest students—culture clashes or misunderstandings that can be attributed, in part, to divergent emotional norms.

Motivation

Turning to motivation, researchers have continued to show how agency can take different forms across diverse cultural contexts, and they are now exploring how cultural goals shape choice and decision making as well as impact health and education behaviors (see Kim & Lawrie, [Chapter 10](#), this volume). The idea that agency can come from “the outside”—from attunement to close others and by following social norms and expectations—instead of “the inside”—from one’s internal preferences and by following one’s own personal attitudes and values—remains a challenging idea for many psychological scientists and people in the West in general (e.g., Kitayama et al., 2007; Markus, 2016; Riemer, Shavitt, Koo, & Markus, 2014; Stephens et al., 2009). Given the power of the Western, neoliberal narrative of choice and freedom in the U.S. and among elites around the world, expanding theories of agency and motivation is an uphill battle that involves bucking a deeply inscribed social and political construction. Increasingly, sociocultural analyses reveal that agency does not equal independence; in fact, in many parts of the world and among diverse groups within the United States itself, agency instead equals interdependence (Markus, 2017).

Studies have demonstrated the real-world significance of independent versus interdependent styles of agency and motivating behavior (Riemer et al., 2014). Eom and colleagues (2016), for example, challenged the prevailing assumption that increasing people’s personal concerns about the environment is the best path to promoting proenvironmental behavior. In a study analyzing World Value Survey data from 42 nations, they found that people’s proenvironmental beliefs were more likely to predict their support for proenvironmental action in countries that are high in individualism, which suggests that the link between belief and action is higher in countries

where “the inside” matters most. In countries that are high in collectivism, such as Japan, where “the outside” matters most, they found that perceived proenvironment social norms were instead more predictive of people’s proenvironmental decisions.

Along similar lines, Ramesh and Gelfand (2010) examined job turnover in India and the United States, two of the world’s most influential economies. While it is important to employees in both India and the United States to feel like they “fit” with their respective companies or organizations, different aspects of fit actually predict job turnover (Ramesh & Gelfand, 2010). In the United States, a country high in individualism, with a culture that values “the inside,” employees are more likely to leave their jobs when they feel that their roles do not fit them personally. In India, a country high in collectivism, with a culture that values “the outside,” employees are more likely to leave their jobs when they feel that they do not have strong connections with other people in the organization.

Looking at studies in education, research has shown that some students are motivated to succeed in school by their connections with others rather than their own individual goals and preferences (e.g., Covarrubias et al., 2016; Fu & Markus, 2014; Stephens et al., 2012). Fu and Markus (2014), for example, found that while Asian American students feel more interdependent with their mothers, and feel more pressure from them to succeed than do their European American peers, this pressure does not put a strain on their relationships or undermine their motivation. Stephens and colleagues (2012) showed that first-generation college students (i.e., students who are the first in their families to attend college) face an unseen disadvantage at many American colleges and universities due to the high value that these schools place on students’ individualism and independence. First-generation college students frequently hail from working-class worlds in which “the outside” is valued more than “the inside,” and their educational and learning goals are more collectivistic and interdependent than individualistic and independent, resulting in a cultural mismatch.

Growing Up: Psychological Development

Given that the cultural and the psychological make each other up, it follows that culture should play a powerful role in psychological development. Researchers who study culture and development have been making theoretical and empirical strides over the past decade, proposing models of cultural variation in development and producing compelling empirical demonstrations of how culture interacts with a variety of developmental processes (see Keller, [Chapter 15](#), this volume).

The last decade of research reveals multiple pathways for healthy human development that are informed by diverse cultural and ecological models of the self, childhood, and familial relationships (e.g., Keller, 2013; Keller & Kärtner, 2013; Schröder, Kärtner, Keller, & Chaudhary, 2012; Q. Wang, 2008); different ways of conceptualizing how children learn by participating in cultural ways of life (e.g., Rogoff, Mejía-Arauz, & Correa-Chávez, 2015; Rogoff, 2014; Tobin, Hsueh, & Karasawa, 2009); and changing norms around development as societies evolve and respond to global trends such as formal schooling and technology use (e.g., Greenfield, 2009; Manago, 2015; Park, Twenge, & Greenfield, 2014).

As an example of this research, Kärtner, Keller, and Chaudhary (2010) studied how culture can foster different pathways to the same developmental milestones. Specifically, they examined emerging prosocial behavior among German and Indian toddlers. In the West, where developing an autonomous and independent self is the norm, developmental scientists have theorized and found empirical support for the idea that having empathy or showing concern for others necessitates being able to distinguish oneself from another person. This is called “self–other differentiation.” Comparing children from middle-class families in Germany and India, a cultural context where developing a relational and interdependent self is instead the norm, Kärtner and colleagues found that while self–other differentiation was associated with increased prosociality among German toddlers, it was not among Indian toddlers. The researchers concluded that there might be another kind of developmental “trigger” in Indian culture, one that does not rely on separating the self from others. Building on the idea that psychological scientists need to question their assumptions about so-called “universal” development processes, research shows that even a number of truisms among Western parents—such as “Beware of stranger danger” or “Don’t play with knives”—are grounded in cultural norms and assumptions

about healthy development that do not hold up in other places around the world (e.g., Lancy, 2016; Marey-Sarwane, Keller, & Otto, 2016).

Externalizing the Psyche: Norms and Morality

We are also learning more about how norms operate across a variety of different cultures, transmitting shared knowledge and guiding moral decision making and behavior. In psychology, “norms” are typically defined as unwritten social rules that guide the kinds of behavior that people find acceptable versus frowned upon. Norms and morals help people answer the “big questions” in a given society, orienting them toward what is good, right, and true and away from what is bad, wrong, and false (Shweder, 1991).

Social and cultural psychologists, as we have noted, ground their scholarship in the theoretical and empirical pursuit of showing the myriad powerful ways the social context influences people’s behavior. The science of cultural norms takes this work even further by analyzing how social norms both perpetuate culture and inspire culture change, and by examining how norms work at both the individual (or micro) and collective (or macro) levels. Studies over the past decade have focused on what shapes the content and strength of cultural norms, when people adhere to rather than deviate from cultural norms, and how social norms can be leveraged to change cultures (Gelfand, 2012; Gelfand & Jackson, 2016; Morris et al., 2015b). While scholars across fields often distinguish between what are called “injunctive norms” (i.e., what people should do) and “descriptive norms” (i.e., what people actually do), researchers have found that this distinction is often blurred among everyday social actors (Eriksson, Strimling, & Coutlas, 2015) or that both kinds of norms often function together as culture operates as shared common sense or as intersubjective perception (Gelfand & Jackson, 2016; Chiu, Gelfand, Yamagishi, Shteynberg, & Wan, 2010; Zou et al., 2009).

Looking at the relative strength of cultural norms across societies, Gelfand and colleagues compared the antecedents and consequences of so-called “tight” versus “loose” cultures (e.g., Gelfand et al., 2011; Harrington & Gelfand, 2014; Mu, Kitayama, Han, & Gelfand, 2015; Roos, Gelfand, Nau, & Lun, 2015). “Tight” cultures are defined as those that have strong norms and

a low tolerance for norm deviance (e.g., Singapore, South Korea), while “loose” cultures are defined as those that have weaker norms and a higher tolerance for norm deviance (e.g., the Netherlands, Israel). In a multilevel analysis of 33 national cultures, they found that nations with a history of ecological uncertainty and threat were more likely to have tight (vs. loose) cultures, which could be explained by a historical need to coherently organize or coordinate social interaction to respond to and survive those threats (Gelfand et al., 2011; Roos et al., 2015; for an analysis of the neurobiology of tightness-looseness, see Mu et al., 2015; for a complementary set of within-nation findings, see Harrington & Gelfand, 2014).

In addition to identifying cross-cultural variation in moral systems and moral judgments, researchers are now focusing on the role of moral behavior in everyday practice and cultural conflicts, as well as investigating differences among subgroups within national cultures (e.g., Buchtel et al., 2015; A. Cohen, 2009; Graham, Meindl, Beall, Johnson, & Zhang, 2016; Oishi, 2010; Piff, Stancato, Côté, Mendoza-Denton, & Keltner, 2012; Rai & Fiske, 2011; see also Miller, Wice, & Goyal, [Chapter 16](#), this volume). Haidt and Graham’s moral foundations theory has been particularly influential, organizing moral differences along six dimensions: harm/care, fairness/reciprocity, liberty/oppression, ingroup/loyalty, authority/respect, and purity/sanctity (Graham et al., 2013; Haidt & Graham, 2007). This framework has been useful for explaining differences in liberal and conservative political ideologies that fuel the American “culture wars” (Graham, Haidt, & Nosek, 2009). Whereas conservatives, for example, tend to value the six dimensions equally, liberals value harm/care and fairness/reciprocity above the others (Graham et al., 2009).

Materializing the Psyche: Cultural Products

“Because cultural psychology is the study of both person-shaped cultural contexts and culturally shaped persons,” Lamoreaux and Morling urged in 2012, “the field should include measures of cultural difference at both of these levels” (p. 299). Over the past decade, cultural psychologists have heeded this call, learning more about how to measure cultural patterns and

tendencies outside of the head by analyzing a wide variety of cultural products.

Cultural products are artifacts or tangible objects—such as computers, phones, books or texts, artwork and songs, consumer advertisements and products, or media—that reflect and reproduce psychological tendencies in a given culture (D. Cohen & Leung, 2009; Lamoreaux & Morling, 2012; Morling, 2016; Morling & Lamoreaux, 2008). As such, cultural products both represent and transmit cultural patterns in ideas and values; they also reflect and transmit aspects of both cultural stability and change. In a meta-analysis of 51 studies of cultural products (i.e., books and texts, Internet and e-mail content, magazine and TV ads, press coverage), Morling and Lamoreaux (2008) found that Western cultural products were more individualistic and less collectivistic than East Asian and Mexican cultural products. In a follow-up study, they also found that cultural products reflected a number of other dimensions of cultural difference beyond individualism and collectivism (Lamoreaux & Morling, 2012). Japanese cultural products, for instance, scored lower than U.S. products on positivity and hedonism, mirroring cultural variation in self-concept and ideal affect.

In recent years, researchers have catalogued cultural differences in self-concept, ideal affect, cognitive style, equality, and power by analyzing children's books (e.g., Imada, 2012; Dehghani et al., 2013; Tsai, Louie, Chen, & Uchida, 2007a), greeting cards (e.g., Choi & Ross, 2011; Koopmann-Holm & Tsai, 2014), religious texts (e.g., Tsai, Miao, & Seppala, 2007b), artwork (e.g., Masuda et al., 2008; Nand, Masuda, Senzaki, & Ishii, 2014), advertising appeals (e.g., Shavitt, Johnson, & Zhang, 2011), and even academic presentations (H. Wang, Masuda, Ito, & Rashid, 2012). In addition to showing how cultural products reflect enduring cultural differences, they have also found evidence of how cultural products can be used to study cultural change (Morling, 2016). DeWall, Pond, Campbell, and Twenge (2011), for example, found that popular American song lyrics have become more self-involved over time. To do so, they looked at word use in the most popular American songs between 1980 and 2007, and found that heightened self-focus and decreased social connection—two common trends in the U.S. during that time period—were reflected in lyrics that increasingly communicated anger and antisocial behavior.

Multiple Cultures: Multiculturalism and Cultural Learning

Psychologists are also learning more about how to theorize and empirically demonstrate the ways that multiple cultures interact, clash, and combine to shape people's psychological experiences. In today's globalized world, interacting with multiple, intersecting cultures at a rapid rate is increasingly the norm for most people, not just immigrants, sojourners, or those with multicultural backgrounds. Moreover, many countries, such as the United States, are also experiencing significant demographic shifts within their borders. Analyzing the impact of these social forces requires more dynamic, interactive, and complex ways to describe and study how the cultural influences the psychological.

In the past decade, research on multicultural identity, cultural priming or frame switching between multiple cultures, multiculturalism's influence on creativity and innovation, and people's acculturation and adjustment experiences as they transition to new cultures have continued to thrive (e.g., Benet-Martínez & Hong, 2014; Chiu & Cheng, 2007; Chiu & Kwan, 2016; Y. Hong, Zhan, Morris, & Benet-Martínez, 2016; Morris et al., 2015a; see also Leung & Koh, [Chapter 21](#); Mesquita et al., [Chapter 19](#), and Chiu & Hong, [Chapter 26](#), this volume). Other research on this topic has looked at how people who are multicultural in various ways think about race and experience discrimination and exclusion, as well as how different kinds of ideologies about diversity and multiculturalism affect people's behavior as well as organizational and social policies (e.g., Chao, Hong, & Chiu, 2013; Cho, Morris, Slepian, & Tadmor, 2017; Rosenthal & Levy, 2012; Sanchez-Hucles & Davis, 2010; Tadmor, Chao, Hong, & Polzer, 2013). Researchers have also examined the psychological processes and outcomes of cultural learning, or how people acquire culture-related knowledge (see Leung & Koh, [Chapter 21](#), and Morris, Fincher, & Savani, [Chapter 18](#), this volume).

Taking a look at recent research on cultural learning, Ang and colleagues, for example, have studied what they call "cultural intelligence" or CQ: the capacity to "adapt effectively to situations of cultural diversity" (Earley & Ang, 2003, p. 3). Building on this work, Leung and colleagues have also identified "cultural metaknowledge" or "knowledge of people's knowledge in a certain culture rather than general knowledge about the culture itself" as another important component of cultural learning (Leung,

Lee, & Chiu, 2013, p. 993). Mor, Morris, and Joh (2013) found that a particular kind of cultural metaknowledge, “cultural perspective taking,” or considering how another’s cultural background shapes one’s behavior in a particular situation, can promote cooperation with people from other cultures. This work takes the idea of cultural competence into the psychological domain, moving beyond a more traditional skills-based framework to unpack the underlying psychological processes involved in learning about culture and cultural differences.

To capture more fully how intercultural contact is an essential part of being human, Morris et al. (2015a) have proposed that psychological scientists adopt a “polycultural” perspective on culture, which is “a network conception of culture in which cultural influence on individuals is partial and plural and cultural traditions interact and change each other” (p. 634). While most scholars in the field would certainly agree with this perspective, Morris and colleagues urged cultural psychologists to recognize that some current theoretical models and empirical paradigms still communicate a categorical and stable view of culture, even if this is not their intent, and that this can have detrimental consequences for the field. Researchers have also started to study how thinking about culture as “polycultural” influences laypeople’s attitudes and behaviors. For instance, Cho and colleagues (2017) found that priming a “polycultural mindset”—or the belief that cultures interact with one another, change, and evolve—can encourage people to prefer consumer products that promote cultural fusion (e.g., English tea blended with Chinese herbs).

Spanning these recent empirical advances and bodies of work, it is clear that researchers are becoming more sophisticated at analyzing cultural and psychological dynamics across multiple levels of analysis—across groups, individuals, and situations—to better understand their processes and mechanisms (Q. Wang, 2016; see D. Cohen, [Chapter 6](#), this volume). They are also diversifying the kinds of cultures, culture clashes, and cultural divides under study, and this is inspiring new questions about how the cultural and the psychological interact (A. Cohen, 2009; see [Part V: Different Forms of Culture](#), this volume). Finally, as we have highlighted throughout this chapter, scholars are even more broadly and deeply investigating how culture is at work in the world, from issues of mental and physical health, workplace diversity, educational equity, and policymaking (in this volume,

see [Part IV: Culture and Economic Behavior](#); Miyamoto et al., [Chapter 12](#); Chentsova-Dutton & Ryder, [Chapter 14](#)). In this vein, we can consider what a cultural psychology perspective could add to organizational studies and also to investigating the professions more deeply as forms of culture (e.g., teaching, policing, coding; Adler & Aycan, 2018; Cheryan, Plaut, Handron, & Hudson, 2013; Master, Cheryan, & Meltzoff, 2016).

LOOKING AHEAD: FROM CULTURE CLASHES TO CULTURE CHANGE

Looking back at the research examples we highlight in [Figure 1.1](#), as well as throughout this chapter, it is hard to deny the myriad compelling ways that culture is at work in the world and in our psychology. As cultural psychology has continued to thrive as a field over the past decade, both deepening and broadening our understanding of how our cultures and our psyches make each other up, people in societies around the world have experienced the power of cultures clashing and interacting at ever-increasing rates. Our headlines and social media feeds are increasingly populated with news of culture clashes or cultural divides that take place within organizations, within nations, and across geographic borders. From gender clashes in Silicon Valley tech companies such as Uber and Google, to race clashes between the police and communities of color in American suburbs and cities such as New York City and Ferguson, to political clashes between conservatives and progressives in recent elections and on college campuses, to religion clashes between Muslim diaspora groups and their European and American host communities, cultural differences—and, most often, cultural misunderstandings—frequently play a leading role (Markus & Conner, 2014).

At the heart of these culture clashes are questions about how to understand the meaning and nature of social differences, as well as how to understand the ways in which social differences more often than not manifest as forms of inequality and marginalization (e.g., Adams, Dobles, Gómez, Kurtiş, & Molina, 2015; Adler & Aycan, 2018; Markus, 2008; Markus & Moya, 2010; Omi & Winant, 1986/2015; Salter & Adams, 2013). Given the demographic changes, cultural interactions and hybridizations,

and shifting power dynamics that people in societies around the world confront every day, we ask how psychological scientists can leverage insights from cultural psychology to help shed light on these issues. In particular, we propose that cultural psychologists are uniquely positioned to (1) reveal and explain the psychological dynamics that underlie today's most significant culture clashes and (2) suggest ways to change or improve cultural practices and institutions to foster a more inclusive, equal, and effective multicultural society.

The issues we highlight here are certainly not new, and they have motivated many a budding cultural psychologist to take up the field. We do, however, propose that incorporating the current trend toward intervention studies in social psychology will provide even more useful theoretical and practical insights for the field and its applications. In the words of psychologist Walter Dearborn, also commonly attributed to Kurt Lewin, "If you want to understand something, try to change it" (in Bronfenbrenner, 1979, p. 37). Social psychologists have taken up this mantle with renewed vigor in recent years as researchers have worked to show how using key social-psychological insights to design brief, targeted, "wise" interventions can produce lasting and meaningful behavior change in diverse domains such as education, health, and politics (for reviews, see G. Cohen & Sherman, 2014; Walton & Wilson, 2018; Yeager & Walton, 2011). Extending these learnings from the psychological science of intervention, how can we apply this perspective to not only behavior change but also culture change?

Since the cultural and the psychological necessarily make each other up, one way to change minds and behaviors is to change cultures, just as one way to change cultures is to change minds and behaviors. It is important to note that this kind of intentional or strategic culture change differs from other significant work in the field on cultural evolution or long-term culture change (e.g., Greenfield, 2009, 2013; Grossman & Varnum, 2015; Varnum & Grossman, 2017; Twenge, Campbell, & Gentile, 2012a, 2012b). While research in this area is primarily concerned with how cultures shift, change, or evolve across time, we ask here: How can targeted, "wise" interventions in the culture cycle help people address today's most significant cultural clashes and combat inequality? So far in this chapter, we have used the culture cycle as a tool to conceptualize the dynamic processes through which the cultural and the psychological mutually constitute one another (Figure 1.2). We have

also used the culture cycle to represent the power dynamics and downward constitution at play in historically derived resource and status differences among cultures and social groups (Figure 1.4). Here, we apply the culture cycle to unpack the psychological dynamics that underlie two timely culture clashes prevalent on college campuses and in the media today, and suggest how we can strategically intervene in the culture cycle to foster more effective and inclusive practices and institutions to address these clashes. These clashes include the experience of first-generation college students from predominantly working-class backgrounds transitioning to the middle- to upper-class culture of higher education, and the fractured relationship between law enforcement and communities of color in U.S. cities and suburbs.

To analyze culture clashes using the culture cycle and identify or target key areas within the cycle to initiate or catalyze culture change, we propose starting by considering the following set of orienting questions (Figure 1.5).

Ideas: How are social differences (e.g., nation, social class, race or ethnicity, gender) conceptualized or represented at the ideas level in terms of norms, values, and ideologies?

- Are social differences conceptualized as internal, essential, and as deficits or as contextual, adaptive, and as assets?
- Do pervasive ideas reflect a commitment to color blindness, multiculturalism, or polycultural ideologies? Are they a blend or mixed?

Institutions: How are social differences formalized at the institutional level in terms of policies, organizational structures, or features?

- Are social differences reinforced as deficits or as assets through institutional dynamics, policies, structures, and features?
- Do institutional policies, structures, or features ignore, reinforce, or contest difference?

Interactions: How are people or groups interacting with one another with respect to social differences?

- Are social differences treated as assets or deficits through formal and informal practices, relational dynamics, and artifacts that people encounter in daily life?
- Do people identify with particular social groups? If so, how? How important are they for people's identities?

Individuals: How are people experiencing their own and others' social differences?

- Are social differences experienced as inferior, irrational, abnormal, misunderstood, and excluded, or valued, rational, normal, understood, and included?
- Do people feel threatened or empowered when their identity is salient?

Cross-level questions:

- Is there a consensus or lack of consensus in the cultural context about how to answer the previous questions?
- How do the four levels work together? Are they relatively aligned or misaligned?

FIGURE 1.5. Understanding culture clashes and targeting culture change.

Using the culture cycle to map culture clashes and identify places to intervene in the culture cycle, it is important to keep several points in mind. As we noted previously, all four levels of the culture cycle are equally influential—none is assumed to be more significant or powerful than the others as they work together in a dynamic, mutually constituting system. When it comes to culture change, however, culture changers need to consider whether the levels are working together to reinforce or buttress one another, or whether they might be working against one another, causing spots of tension and misalignment (e.g., Coyle, 2018; Gibbons, 2015; Kotter, 2012; Morgan, 2006; Porras & Silvers, 1991). They also need to consider whether people within a given culture, and among the different levels, have consensus or a shared understanding of what is taking place and why in a given setting. Furthermore, given that psychologists are typically trained to focus on the individual, and also sometimes the interactional levels, they tend to zero in on changing people’s mindsets or construals without fully considering how these micro- or meso-level changes might interact with the larger institutional and social forces at play. On the other hand, practitioners and policymakers often focus on these macro-social and institutional factors and, in turn, do not pay close enough attention to the interactional and individual levels. As cultural psychologists, we can work to take a more holistic, interactive, and dynamic approach that considers each of the levels in tandem. Thinking through the questions we present in [Figure 1.5](#) can help scholars and practitioners alike unpack the sources of culture clashes and divides, as well as think through where they might wisely catalyze or coordinate culture change efforts.

- *Culture clash 1: First-generation or working-class college students in middle-to-upper class college and university settings.* The first culture clash that has garnered a lot of attention in recent years at colleges and universities around the country. First-generation college students—or students who are the first in their families to go to college—often experience a clash between their working-class upbringings and the middle- to upper-class culture of higher education, especially at elite schools. Recent research reveals that the culture of U.S. higher education is not neutral. It both reflects and promotes class-based norms, values, and assumptions about what it means to be “smart,” “educated,” and “successful” (Fryberg et al., 2013; Quaye & Harper, 2015; Stephens et al., 2012). As a result, first-generation students often feel excluded or different from others in college settings, which can lead them to question whether they fit or belong (Covarrubias & Fryberg, 2015; Ostrove & Long, 2007; Walton & Cohen, 2007). Students from low-income or working-class backgrounds may also be unfamiliar with the “rules of the game” that are needed to succeed in higher education, which can undermine their sense of empowerment and efficacy (Housel & Harvey, 2009; Ostrove & Long, 2007; Reay, Crozier, & Clayton, 2009). As such, typical college environments can systematically disadvantage first-generation students, contributing to an achievement gap with their continuing-generation peers (i.e., students who have at least one parent with a 4-year degree; Astin & Oseguera, 2004; Bowen, Kurzweil, & Tobin, 2005; Croizet & Millet, 2011; Goudeau & Croizet, 2017; Sirin, 2005; Stephens et al., 2012). These kinds of psychological challenges work alongside disparities in resources and precollege preparation to fuel the social class achievement gap.

Where in a college or university’s culture cycle might we intervene to make its values, policies, and practices more inclusive of and equitable for first-generation students? Research in social and cultural psychology shows that educating students about how their social class backgrounds can shape their college experiences, teaching students to understand how social differences can be an asset, and changing college norms to be more interdependent and collectivistic (vs. independent and individualistic) can be effective intervention strategies that foster academic and social success for first-generation students (Dittmann & Stephens, 2017; Stephens, Brannon, Markus, & Nelson, 2015; Stephens, Fryberg, et al., 2012; Stephens,

Hamedani, et al., 2014). In particular, these strategies center around helping first-generation students adopt a new lay theory of social difference and experience their backgrounds and perspectives as part of, rather than separate from, the mainstream college environment.

To apply these strategies to change college cultures, we might ask how colleges and universities might address the following at each level of the culture cycle. For example, to help first-generation students feel empowered at the *individual level*, schools could assign first-generation students “big sibs” or mentors that are first-generation graduate students or faculty to help advise them and act as role models (*interactions level*); institute an intergroup dialogue class or counter storytelling workshop requirement for all incoming first-year students that highlights how people’s different social class backgrounds can be resources (*institutions level*); or elevate and normalize interdependent or collectivistic values and academic motivations in college or university promotional materials such as “giving back to your community” (*ideas level*). Ideally, to have the biggest impact, culture change is more likely to progress when there is change at each level and these changes work to support and reinforce one another over time.

- *Culture clash 2: Police–community relations in communities of color.* The second culture clash has a long, fraught history in the United States: police–community relations in communities of color, especially in African American communities. The tense relationship between law enforcement and communities of color is one of the most contentious culture clashes in the U.S. today, with officer-involved shootings of unarmed black male civilians being one of the major catalysts of the modern racial justice movement. Since the rise of Black Lives Matter in response to the shootings of unarmed black boys and men such as Trayvon Martin, Michael Brown, and Akai Gurley, police–community relations are seriously fractured, and many Americans, especially those in low-income communities of color, do not trust the police or believe that law enforcement exists to keep them safe (La Vigne, Fontaine, & Dwivedi, 2017; Morin, Parker, Stepler, & Mercer, 2017; Pegues, 2017). In this climate, there have been numerous calls for police departments around the country to reexamine and change their cultures, which have been called toxic, violent, disrespectful, and macho (Armacost, 2016; A. Hall, Hall, & Perry, 2016). At the same time, many

officers across the country think that the public does not understand the nature of their jobs and the risks that they face (Morin et al., 2017; Pegues, 2017). As such, politicians, law enforcement professionals, and community activists have been grappling with how to bridge the so-called “black and blue” divide. From the effects of implicit racial bias to the tension between so-called guardian versus warrior mindsets, to the use of new technologies such as body-worn cameras, to the implementation of procedural justice and community-based policing practices, police and community members alike are struggling with how to work together effectively and come up with solutions that address concerns on both sides of the divide (e.g., Eberhardt, 2016; A. Hall et al., 2016; Hetey & Eberhardt, 2014; Lyons-Padilla, Hamedani, Markus, & Eberhardt, 2018; President’s Task Force on 21st Century Policing, 2015; Trinkner, Tyler, & Goff, 2016; Tyler, Goff, & MacCoun, 2015; Voigt et al., 2017).

Where in a police department’s culture cycle might we intervene to help increase trust and cooperation among police and community members? On the policing side, law enforcement professionals and researchers alike have proposed the following evidence-based solutions to help police departments evaluate and improve their practices: Develop officers’ procedural justice and community-based policing skills, educate officers about implicit bias, diversify the police force, increase cross-race experience and dialogue, leverage technology to identify disparities and evaluate training initiatives, attend to officers’ social and emotional needs, increase departmental accountability and transparency, and improve internal procedural justice (Eberhardt, 2016; Gilmartin, 2002; A. Hall et al., 2016; Lyons-Padilla, Hamedani, Markus, & Eberhardt, 2018; Pegues, 2017; President’s Task Force on 21st Century Policing, 2015; Tyler et al., 2015; Voigt et al., 2017). In particular, a number of these strategies shift officers away from a warrior mindset that casts black males, in particular, as “enemies” or “others,” to a guardian mindset that is more relational or other-focused and motivated by why many officers joined the police force to begin with—to help people.

To apply these strategies to change the culture of police departments, we might ask how law enforcement agencies can address the following at each level of the culture cycle. For example, to help police officers adopt a guardian mindset (*individual level*), law enforcement agencies could provide more positive opportunities for sworn staff to learn about and interact with

the local communities they serve but sometimes do not live (*interactions level*); reward procedural justice or community-based policing behaviors when considering raises and promotions (*institutional level*); and integrate procedural justice and community-based policing values into departmental strategic plans, missions, and visions (*ideas level*). Ideally, to ensure the strongest impact, culture change will be more likely to progress if law enforcement agencies work on their legitimacy issues with the communities they serve by being transparent and involving community stakeholders in their culture change efforts.

Culture change is difficult work and may have unintended consequences. Culture changers need to keep in mind how the interconnecting, shifting dynamics that make up the culture cycle afford certain ways of being, while constraining or downwardly constituting others, and that this can change or rebalance when intervening in the cycle. Culture changers also need to recognize that in terms of fostering more inclusive, equal, and effective institutions and practices, the deeper work often involves actually changing how people think about the meaning and nature of the social difference (e.g., Markus, 2008; Markus & Moya, 2010).

CONCLUSIONS: CULTURE IS TRENDING

People are culturally shaped shapers. In demonstrating this point, we have ranged from the biological to the societal, reviewing research on genes and also on police–community divides. Across domains, at every level of behavior, people invoke culture as they struggle to make sense of themselves and their worlds. In brief, it is an excellent time to be a cultural scientist, a cultural psychologist, or to add sociocultural analysis techniques to one’s “making sense of behavior” toolkit. The pay is variable, but the work is unlimited and infinitely challenging. And the possibility to make a positive difference in scientific understanding and in the applications of these understandings is real.

The innovative and groundbreaking research reviewed here gives rise to more questions than answers, but the questions are now somewhat different in nature than in earlier decades. Cultural psychological questions are no

longer shadowed by the suspicion that cultural differences are merely superficial or something to be tackled at some point only after basic human functioning has been mapped and described. The psychological is cultural and the cultural is psychological. Culture exists both in the head and in the world; it is made up of both conceptual and material elements; and its influence on the psychological can be analyzed and measured not only through people's reactions and responses, but also through analyses of products, practices, and policies that reflect and promote pervasive cultural ideas. While cultural psychologists have been laboring to refine the field, it has become clear that the world outside of the ivory tower needs their insights and solutions now more than ever.

The phrase "It's cultural" often reveals people's frustration that a problem is messy and intractable, too big and complex to parse and solve. Sometimes people use that phrase as a way to say a problem is systemic, but they often use it to deflect responsibility and say that a problem is not really "our" problem. The good news is that, as highlighted by the work we have reviewed in the chapter, psychologists are now equipped with the theories, methods, techniques, and applications to make it our problem. We think that cultural psychologists are more than ready to take up this challenge.

CHAPTER 2

A History of Cultural Psychology

Cultural Psychology as a Tradition and a Movement

Yoshihisa Kashima

Cultural psychology as embodied in the current edition of the *Handbook of Cultural Psychology* is an intellectual movement located in cultural psychology as an intellectual tradition whose historical roots may be found in the Enlightenment and Romantic schools of thought, and their conceptions of the person, in 18th- and 19th-century Western Europe. The chapter traces their influence in the history of psychology as an academic discipline in the form of natural scientific versus cultural scientific models of psychological investigation—emergence, entrenchment, and ebbing of this structure—in interaction with global history, and describes the historical context in which contemporary cultural psychology appeared as an approach that regards humans as meaning-making beings. The chapter then observes an emerging conception of the person that challenges the Enlightenment–Romantic assumption separating culture from nature, and notes its reflection in cultural psychology’s recent push to naturalize culture in the early 21st century against the backdrop of the global challenges to humanity, including climate change and intergroup conflict. The chapter concludes with a call for new conceptions of the person that regard culture *in* nature, which can help orient cultural psychology for the future.

Cultural psychology has two senses. In one sense, it is an intellectual movement that came into prominence in the late 20th century; in the other

sense, it is a primarily Western European intellectual tradition that has continued since the 19th century. The publication of *Cultural Psychology: Essays on Comparative Human Development* (Stigler, Shweder, & Herdt, 1990) marked the start of the former with Richard Shweder's (1990) essay, "Cultural Psychology—What Is It?" The first edition of the *Handbook of Cultural Psychology* (Kitayama & Cohen, 2007) was very much a product of this movement. However, it finds its inspiration in the early writings of the Romantics of the 19th century. To wit, Shweder's (1984a) essay, "Anthropology's Romantic Rebellion against the Enlightenment, or There's More to Thinking Than Reason and Evidence," links Shweder's thinking on psychological anthropology to the Romantic intellectual tradition, from which cultural psychology as a tradition draws.

In many ways, these two senses of cultural psychology—movement and tradition—are thematically intertwined despite the time that separates them. Yet their implications for the future of psychology may differ a great deal. Believing that a reconstruction of history is most useful when conducted in order to understand the present and contemplate a future, I attempt to outline a history of cultural psychology in these two senses, while bringing out their thematic continuities and discontinuities, so as to point to risks and opportunities for cultural psychology. To anticipate, it is my contention that the role of cultural psychology in the future of psychology depends on how culture, nature, and the person are construed, and how conceptions of the person inform the practice of cultural psychology. The conceptions of the person underlying much of the history of cultural psychology, and indeed psychology more generally in the past, assumed that nature and culture are separate, and even in conflict; however, the concept of culture is now beginning to be *naturalized*—culture is no longer in opposition to nature, but is a critical aspect of human nature—and the changing conception of the person implies that being naturally cultured is what it means to be human.

But for now, we need to go upstream in the latter half of 19th-century Central Europe to begin this time travel.

CULTURAL PSYCHOLOGY AS A TRADITION

Arguably, cultural psychology as an intellectual tradition can find its institutional origin in Moritz Lazarus (1824–1903) and Hajim Steinthal's (1823–1899) publication of the journal *Zeitschrift für Völkerpsychologie und Sprachwissenschaft* in 1860, which may be translated as the *Journal of Cultural Psychology and Philology*. According to Gustav Jahoda (1992), a native speaker of German, the German word *Völkerpsychologie* is difficult to translate to English. Literally speaking, it may be translated as folk psychology, that is, “psychology of a people.” In paraphrasing Lazarus and Steinthal's first article in the journal, Jahoda (1992, p. 148) explains that it was meant to be a study of *Volksgeist*, that is, *Geist* (spirit, mind, or mentality) of a *Volk*, which Lazarus and Steinthal characterized as a group of people who have common “subjective views . . . about themselves, their shared identity and feeling of belonging together” (translated and cited in Jahoda, 1992, p. 149). Roughly speaking, then, *Völkerpsychologie* was a study of collective mental phenomena, or the psychological processes and their products shared by a people.

Historical Backdrop

Cultural psychology in this sense can be seen as an outgrowth from the European intellectual tradition of the 18th and 19th centuries (see Jahoda, 1992). Two broad currents permeate the past three centuries of intellectual discourse, which are often glossed over as Enlightenment and Counter-Enlightenment (or Romantic) thoughts. The age of Enlightenment emerged during the period in which natural science and technology made great strides, and the Industrial Revolution in the 18th century changed the landscape of the production of goods, the provision of services, and the movement of people. The well-known lines attributed to Alexander Pope attest to the optimism and faith heaped on the progress brought about by natural science.

Nature and nature's law lay hid in night;
God said, “Let Newton be,” and all was light.
Nature is dictated by the law of nature; it is science that reveals it.

The Enlightenment conception of the person endows humanity with the innate and universal capacity to reason. That is, *all humans* share the universal rationality. Jahoda (1992, p. 33) translated a prototypical exemplar from *Essai sur les mœurs* by François-Marie Arouet (1694–1778), better known as Voltaire: “God has given us a principle of universal reason, just as he has given feathers to birds and fur to bears; and this principle is so constant that it persists in spite of all the passions that oppose it, in spite of the tyrants wanting to drown it in blood, in spite of the impostors who want to destroy it with superstition.” This passage illustrates the Enlightenment’s epistemic and political dimensions. On the one hand, humans are beings that *naturally* have the capacity for rational reason, which enables humans to think rationally, arrive at the truth, and make a rational decision. Either by rational deduction (i.e., rationalism) or by observation, experimentation, and rational induction (i.e., empiricism), humanity is to uncover the law of nature. On the other hand, because every human has the same universal faculty to reason, everyone is equal. Therefore, the natural law dictates that all humans have the universal and inalienable human rights, and that they should be treated equally—the doctrine that echoes through the Declaration of Independence of the 13 states, the United Nations (UN) Universal Declaration of Human Rights, and so on to this day (see Kashima & Gelfand, 2012).

Nevertheless, confronted by human diversity across the globe—after all, the Enlightenment period was also the age of a European expansion to all corners of the world, for exploration, trade, and colonization—many thinkers of the Enlightenment adopted an explicit or implicit social evolutionary thinking; that is, they believed that all human societies and cultures *progress* through the same stages of evolution over time to higher and more advanced stages. As Klineberg (1980) noted, the Enlightenment’s preoccupation with progress made the social evolutionary thinking a natural explanation of human diversity, placing diverse world cultures into different levels of progress, some as “primitive savages” (or in Rousseau’s case, “noble savages”) and others as “advanced and civilized.” This placement of cultures along a temporal dimension is not, however, the only solution to the diversity problem. Another class of explanation can make use of spatial placements in diverse natural environments as a mechanism for cultural diversification—human cultures are different because they are in different

natural environments (see Jahoda & Krewer, 1997). Whether one takes a temporal or spatial explanation of human diversity, the underlying conception of the person is one of universality: The underlying essence of humanity—rationality—is the same across space and time; it is the temporal or spatial variability that explains their apparent variations.

The counterpoint to the Enlightenment thought is called Counter-Enlightenment, or the *Romantic* thought. Its main source of inspiration is often traced to Giambattista Vico (1668–1744), an Italian political philosopher. In *The New Science*, Vico (1725/1948) portrayed human history not as the linear upward movement of progress, but as a cyclical pattern of progress and regress, going through the divine, heroic, and human phases. His analysis of cultural groups and human history made use of symbolic representations of various forms, including poems, narratives, and arguments (Berlin, 1980). It was then taken up and expanded by German thinkers such as Johann Gottfried Herder (1744–1803), whose philosophy included an emphasis on a national language as an expression of a people and their mentality, and an argument against purely rational thought, as seen in his criticism of Kantian philosophy of pure reason (Barnard, 2003). In this Romantic view, culture represents a deep and unchangeable essence of a people. A people, or a nation, constructs its unique culture with its unique language and unique customs. To put it simplistically, a people share their mentality, which enables them to have a deep understanding of each other's thoughts and actions, and their meaning.

The Romantic thought, too, has both epistemic and political dimensions. Epistemically, Herder introduced the concept of *Einfühlungsvermögen*, “the capacity to feel oneself into” the mentality of a people (Barnard, 2003, pp. 5–6) as critical to an investigation of history. More generally, the investigation of the mores and customs of diverse peoples is to achieve an empathic understanding (*Verstehen*) of these peoples through their languages, arts, and symbolic creations. Because a people constitute their culture, and a culture, a people, it is only through an empathetic understanding of their culture that one can fathom their mentality—not just rational reason, but also emotionality, aspirations, and purposes—and their way of life. Politically, this conception of the person can have a nationalistic implication, though it is not a logical necessity (Kashima & Gelfand, 2012; see Barnard, 2003, on Herder's political philosophy as a complex mixture of nationalism

and humanism). That is to say, those who share their culture and mentality belong to a nation, but those who do not, do not, thereby drawing a sharp boundary around the group that shares a culture in clear exclusion of the others who do not.

Psychology as Natural Science or Cultural Science

The cultural divide between the Enlightenment and the Romantic intellectual traditions has played out in the history of psychology as epistemological and methodological controversies. It was probably Wilhelm Dilthey (1833–1911) who formulated this most clearly. By contrasting *Naturwissenschaften* and *Geisteswissenschaften* (sometimes translated as “natural sciences” and “human sciences”), Dilthey (1883/1988) suggested that what we now call “humanities” and “social sciences” are to be distinguished from natural sciences in his *Einleitung in die Geisteswissenschaften* (originally published in 1883), which Betanzos (1988) translated as *Introduction to the Human Sciences*. In introducing the term, *Geisteswissenschaften*, or “sciences of the mind,” Dilthey justified their distinction from natural sciences by citing

the depth and fullness of human self-consciousness. . . . [A] man finds in this self-consciousness a sovereignty of will, a responsibility for actions, a capacity for subordinating everything to thought and for resisting any foreign element in the citadel of freedom in his person: by these things he distinguishes himself from all of nature. [T]he actions of the will—in contrast with the mechanical process of changes in nature . . . —really produce something and achieve true development both in the individual and in humanity as a whole. (p. 79)

To Dilthey, it was self-reflexive agency—or what appears to be the operation of the agentic and spontaneous mind—that distinguished the realm of human activities and the sociohistorical processes that they generate.

Dilthey begins his analysis from the “psycho-physical” individual, who is at once a physically embodied and mentally self-aware being. He characterizes psychology as a scientific discipline that examines this human individual. Dilthey recognizes human individuals as subject to and contributing to both the natural processes and to the processes of human activities and their products cumulated over the course of history. Noting that the whole of “historico-social life” consists of those sociohistorically

situated human individuals' purposive activities, he first distinguishes a *system of culture*, complex dependencies among those purposes discernible from concrete human individual actions. As an example of such “purpose-complexes,” he alludes to religion—an analysis of a religion and its dogmas is to uncover “how dependence of dogmas on one another is grounded in the nature of religion” (Dilthey, 1883/1988, p. 103). Next, Dilthey distinguished the *external organization of society*, which he characterized as “the structure which arises out of an association of wills, . . . communities, . . . associations, and . . . the framework which arises out of relationships of domination and external constraint of will” (1988, p. 104). These roughly correspond to the domains of investigation of what we now call anthropology and sociology. To him, human sciences were to consist of the trifecta of psychology, anthropology, and sociology thus conceived.

At the expense of oversimplification, let me provide a thumbnail sketch of the two models of psychology that Dilthey's *Naturwissenschaften* and *Geisteswissenschaften* exemplify (see [Table 2.1](#)). On the one hand, epistemologically, the natural science model takes an empiricist (or *positivist*) stance, where observations of a subject matter are regarded as primary. Logical positivism of the Vienna Circle, and its counterpoint, Popper's falsificationism, may be regarded as prototypical examples of this school of thought. Using physics as a model, universal laws are to be axiomatized, hypotheses are deduced by propositional logic, tested against empirical observations—especially within experiments—and theories are verified (logical positivist verificationism) or falsified (Popperian falsificationism). The goal of research in the natural science model has been the establishment of causal explanations of psychological phenomena. The key concept here is causality—how a cause produces an effect, and how psychological process emerges from a complex interaction among cause–effect relationships. This is a familiar model for those who have been trained in contemporary personality and social psychology. It is a *de facto* model of psychological inquiry.

TABLE 2.1. Schematic Contrast between Natural and Cultural Science Models of Psychology

	Natural science model	Cultural science model
Intellectual background	Empiricism	Interpretivism
Theoretical presupposition	Universality	Particularity
Goal of investigation	Explanation	Understanding (<i>Verstehen</i>)
Key concept	Causality	Intentionality
Method of investigation	Experimentation	Hermeneutics
Ontology	Materialism	Idealism

On the other hand, the cultural science model takes what may be called an *interpretivist* stance. It takes interpretation of human cultural artifacts (e.g., languages, poems, stories, paintings, music, rituals) as a starting point of inquiry and by means of hermeneutic or semiotic methods, an inquirer develops a theoretical interpretation, or potentially even an empathetic understanding, or *Verstehen*, of the subject matter. Simply put, the goal of inquiry has been to bring out the *meaning* discernible in human action and its product in the cultural science model. Geertz (1973), Taylor (1971), and Ricoeur (1971) are proponents of this line of thinking, and they championed the “interpretive turn” (Rabinow & Sullivan, 1979) in social sciences and humanities. Universality tends to recede in the background, and what is often emphasized is the particularity of a people and their culture. The key concept here is “intentionality”—how a mind is directed toward things, events, and the world, and how it captures the meaning of the object of construal and the world in which it is situated. This model tends to encourage the use of qualitative methodology—ethnographic observations, interviews, and systematic investigations of texts, paintings, or any other forms of cultural artifacts.

Implicitly underlying these methodological and epistemological differences was a metaphysical opposition between materialism and idealism. The natural science model has tended toward a materialist view—human beings are nothing but material beings, and human minds are something like “machines” that carry out operations. Culture then supplies a mere content that is processed by the material mechanisms. The cultural science model has tended toward an idealist view, regarding human mind

and culture—ideas and meaning—as constituting a stratum that is essentially different from the material objects and substances. This stance tends to imply a kind of mind–body dualism. For, if the mind consists of something that is not material, it must be made of something else.

There is, however, one presupposition that the two models of psychological inquiry seem to share. That is the fundamental *separation between culture and nature*. This can be best understood as the conception of the person—an understanding about what it means to be human—that they both presuppose. In the natural science model, culture is an add-on; it is regarded as something that makes a surface difference grafted on top of the deep universal human nature. In contrast, in the cultural science model, culture is essentially human; culture and meaning largely constitute the person. Nonetheless, in its tenacious gaze at the cultural, the material brain, body, and organism—the natural, if you like—tend to recede in the background of inquiry. It follows then that the natural science model is inclined to exclude culture from the core domain of inquiry, whereas the cultural science model would regard culture as its central concern.

These general ideas and practices have been embodied in the quantitative and qualitative research methods, and the methodological differences continue to exist in contemporary psychology. One terminological caveat is in order, however. When I say empiricism, I use the term in the sense of the British empiricism of Locke, Berkeley, and Hume, not in the broader sense of respect for data. In this latter sense, both natural and cultural scientific approaches, and quantitative and qualitative methods, can be (and dare I say, should be) empirical. What is noteworthy is that the intellectual traditions of the Enlightenment and Counter-Enlightenment resonate through to this day in the ideas and practices of psychological research. These cultural legacies exist in contemporary writings and the conduct of psychological inquiries, and from time to time, differences in these ideas and practices emerge in the form of theoretical debates. Nonetheless, it is probably fair to say that mainstream psychology, understood as the majority of psychology programs at university departments, has adopted the natural science model, and for much of the history of psychology, the cultural science model has survived at the periphery of psychology as an academic discipline.

CULTURE IN PSYCHOLOGY

Wilhelm Wundt (1832–1920) is credited to have established the modern academic discipline of psychology when he founded the first laboratory of psychology in 1879, at the University of Leipzig. He conducted experimental research on consciousness by introspection and also engaged in research on a variety of cultural products including myths and folktales. His overall conception of psychology may be discernible in his introductory book on psychology called *Outlines of Psychology* (Wundt, 1897/1907). He draws a sharp distinction between the method of analysis for mental *processes* and the method of analysis for mental *products*. He argues that experimentation is possible for introspective psychology; however, it is also possible to observe the mental products such as speech, myths, and customs, because they are more or less enduring objects produced by collective processes. His mental products (e.g., speech, myths, and customs) are to be interpreted. In this writing, he regarded the latter to be investigated by social psychology—not unlike contemporary research on cultural artifacts. Thus, he embraced not only the natural science model of psychology but also the cultural science model of psychology. This latter aspect was called *Völkerpsychologie*, or folk psychology.

Nevertheless, it appears that his folk psychology was not to be an investigation of the unique mentality of a people, but rather an attempt to uncover the “law of history” of humanity. Not unlike his contemporary social evolutionists, Wundt appears to have believed that human history has its indigenous regularity—in the last sentence of his *Elements of Folk Psychology: Outlines of a Psychological History of the Development of Mankind*, he wrote, “Humanity . . . included within itself all antecedent social phenomena—peoples and States, religion and culture. This entire social complex has been subsumed under the principle that law is immanent in all history” (1916, p. 523).

Still, it is noteworthy that elements of Dilthey’s *Naturwissenschaften* and *Geisteswissenschaften* were both present at the official start of psychology as an academic discipline.

In retrospect, the Interwar era of the 1920s and 1930s was a significant period for culture in psychology. It was not necessarily in the academic discipline of psychology that many of the significant developments took

place in the works of Lucien Lévy-Bruhl (1857–1939) in France, Frederick Bartlett (1886–1969) in the United Kingdom, and Lev Vygotsky (1896–1934) in Russia. Also noteworthy is Sigmund Freud’s (1856–1939) psychoanalysis. Although the psychoanalytic influence has waned in contemporary culture and psychology, Lévy-Bruhl’s, Vygotsky’s, and Bartlett’s work has contemporary resonance and are briefly touched on below.

Based on the Durkheimian notion of collective representations, Lévy-Bruhl (1922/1923, 1985/1910) argued that Western collective representations or cultures emphasize the law of contradiction according to which A and not A cannot be true at the same time; therefore, concepts are defined as mutually exclusive; in contrast, “primitive” cultures emphasize the law of participation in which A and not A can both be true at the same time, and concepts are understood as mutually complementary. When the use of the term “primitive” is discounted (and the racist connotation ignored), his theory can be construed as a precursor to contemporary cognitive and symbolic anthropology (Littleton, 1985), and finds a more recent counterpart in cultural psychology in the research on naïve dialecticism (Peng & Nisbett, 1999).

Vygotsky’s (1978; also see Wertsch’s [1985] scholarly explications of his work) influences are substantial, not yet in personality and social psychology, but already in developmental psychology and education. Best known insights from his work include the idea that children acquire adults’ cognitive skills and practices as they work together with their caretakers using psychological tools *in situ*, and that children have a “zone of proximal development,” which defines the area of cognitive and motor activities that they can learn with more skilled others’ scaffolding—when a skill is outside this area, a child cannot learn it even with practice. The strongly situated nature of his theorizing—an influence from Marx’s theory of praxis—finds its contemporary expression in Michael Cole’s (1996) cultural psychology.

Bartlett (1923) is better known as the cognitive psychologist who introduced the schema concept to memory research in his classic *Remembering* (Bartlett, 1932). However, inspired by his mentor, an anthropologist, W. H. R. Rivers, he regarded remembering as fundamentally cognitive and as social processes in which original information is interpreted and later reconstructed for reproduction. Whereas Bartlett’s

work has laid foundation for cognitive psychology, the relevance of his work for contemporary culture and psychology is now recognized (Kashima, 2000a) both in the theoretical formulation of dynamic constructivism (Hong, Morris, Chiu, & Benet-Martínez, 2000) and in empirical research with the method of serial reproduction (Kashima, 2000b) in which the transformation of cultural information is explored as it is transmitted from one generation to next.

Despite these pioneering works, culture was very much out in the cold within the academic scene of psychology. Cole (1996) observed that when Boring (1950) wrote a 777-page tome, *A History of Experimental Psychology*, he expended one sentence on Wundt's *Völkerpsychologie*. In fact, the period of the 1930s to the 1950s coincided with the heyday of behaviorism by John B. Watson (1878–1958) and B. F. Skinner (1904–1990), with their exclusive emphasis on the observables and theoretical descriptions of psychological processes in terms of external stimulus or reinforcement on the one hand and behavior on the other. While logical positivism and behaviorism, and the natural science model of psychology with them, became a dominant paradigm in psychology, so much so that culture and meaning, and indeed the concept of mind itself, was pushed to the periphery or outside of the academic discipline of psychology in the form of Freudian psychoanalysis and its offshoots, the object relations.

In the meantime, the narrative of Enlightenment (Progress!) would have looked very much like the right description of human history, at least from the Western European perspective. After World War II ended in Japan's defeat in 1945, the world entered a period of relative calm. Science and technology were providing greater powers and increasing human control over the environment, although the Cold War and the threat of a nuclear winter acted as a reminder of its potential danger. Whichever side of the Iron Curtain one was on, the signs of scientific advances and material prosperity were increasingly visible in the 1950s and 1960s. The year 1957 saw the orbiting of Sputnik 1 around the Earth and the start of the Space Race; the mass production of consumer goods became a standard order, and domestic goods and services—cars, TV sets, and other appliances—became increasingly accessible to a greater proportion of society, at least in the so-called First World (Western Bloc), and perhaps to a lesser extent in the Second World (Eastern Bloc).

The natural science model of psychology predominated throughout this period. Although the Cognitive Revolution—by Jerome Bruner, Noam Chomsky, Roy D’Andrade, and others, to name a few—brought the mind back in the 1960s, cognition was construed very much in the vein of the natural science model of psychology. The von Neumann serial computer provided a powerful metaphor of the mind—the universal hardware driven by the Central Processing Unit manipulates symbols, and software can be written to program the computer to do human-like operations even more efficiently than the human mind itself. According to Bruner (1990), the aim of the Cognitive Revolution was “to discover and to describe formally the meanings that human beings created out of their encounters with the world, and then to propose hypotheses about what meaning-making processes were implicated. It focused upon the symbolic activities that human beings employed in constructing and in making sense not only of the world, but of themselves” (p. 2). He laments that its impulse was “technicalized,” for instance, as its emphasis began to shift from the construction of meaning to the processing of information (p. 3).

INTERSECTION OF CULTURE AND PSYCHOLOGY IN THE 1940S–1970S

This is not to say that there was no academic research on culture and psychology between the 1940s and the 1970s. While psychology as an academic discipline has largely adopted the natural science model as its *modus operandi* and moved out of culture, the Boas–Sapir school of North American anthropology began to explore the intersection of culture and psychology. Of these two, the latter has a more direct influence on the contemporary development in cultural psychology. Broadly known as Culture and Personality, this area of research took Freudian psychoanalysis as a source of inspiration and made some classic contributions to the area. Margaret Mead (1928), Ruth Benedict (1934), Kardiner (psychiatrist) and Linton (anthropologist) (Kardiner & Linton, 1944; Kardiner, Linton, Du Bois, & West, 1945), John Whiting and Irvin Child (1953), Anthony Wallace (1961), and others began to examine culture’s influence on personality (Mead), personality’s influence on culture (Benedict, so to speak), and the

interaction of the two (Kardiner & Linton). Regarding both culture and personality as *integrated systems*, they sought to characterize them as some form of *central tendency* in the distribution of patterns of behaviors, whether one calls them basic personality structure (Kardiner), modal personality structure (Wallace), or custom complex as a configuration of customary behaviors performed by a typical member of a culturally defined category of persons (J. Whiting & Child).

Without going into a great detail, a brief sketch of Kardiner and Linton's (1944) broad scheme may help convey the general contour of their theorizing. They distinguish between society and culture: "A society is a permanent collection of human beings; the institutions by which they live together are their culture" (p. 7). By institution, they mean "any fixed mode of thought or behaviour held by a group of individuals . . . which can be communicated, which enjoys common acceptance, and infringement of, or deviation from which creates some disturbance in the individual or in the group" (p. 7). They distinguished between primary and secondary institutions, and postulated *basic personality structure* that is common to the group as a mediating mechanism between the two. The primary institutions largely consist of the child-rearing practices (i.e., how children are socialized), while not completely neglecting the importance of subsistence systems, as in the ecological approach. The basic personality structure is seen to be a psychological adaptation to the primary institutions. The secondary institutions are a variety of symbolic forms such as art and religion. While Linton regarded culture as a system of social heredity that is transmitted across generations, Kardiner understood the basic personality structure as a deep psychological stratum conceptualized in line with Freudian psychodynamics. The projections of the basic personality structure constitute the secondary institutions, which in turn satisfy the psychosexual needs and desires experienced by the basic personality structure.

In the 1960s and 1970s, several research programs began to develop at the intersection of culture and psychology. Surveying this development, Jahoda (1980) listed seven broad programs. Although all are of historical significance in their own right (e.g., cross-cultural research on Piagetian cognitive development, cross-cultural research on achievement motivation), only three are selected, renamed, and somewhat modified for further

discussion here because of their direct relevance for the current literature on culture and psychology in the early 21st century.

Ecological Approach

Researchers began investigating the impact of ecology on psychological processes, especially perception. Following the pioneering work by such notable researchers as Rivers (1901), and Allport and Pettigrew (1957), Segall, Campbell, and Herskovits (1966) undertook a project in which susceptibility to perceptual illusions such as Müller-Lyer, perspective drawing, and horizontal-vertical illusions was investigated. They conducted experiments in several different areas of sub-Saharan Africa, as well as in North America, with varying degrees of exposure to the cultural artifacts in which the built environment consists of vertical and horizontal straight lines intersecting with each other at right angles (“carpentered-world”) and the three-dimensional perceptual experiences being represented in two-dimensional space (perspective drawing). They reported strong support for the hypothesis that Western people are more susceptible to these perceptual illusions than non-Westerners.

Further inquiring into the ecological and cultural impact on perception, a productive line of research emerged exploring field-dependent and independent cognitive style (e.g., Witkin, 1967; Witkin & Berry, 1975). Field independence (vs. field dependence) means that perception and cognition are not very much influenced by context. So, for instance, when people are required to adjust a rod vertically when it is placed within a tilted frame (rod-in-frame test), field independents make fewer errors than do field dependents (see Witkin, 1967). Furthermore, cultural groups that showed perceptual field independence were often found to exhibit social independence in the Asch-style social conformity task (e.g., Berry, 1968). The conceptual and empirical link between perceptual field independence and social independence is particularly intriguing in light of the fact that Solomon Asch and Herman Witkin’s research on context effect on perception (Asch & Witkin, 1948a, 1948b; Witkin & Asch, 1948a, 1948b) gave rise to the theory and research on field independence and dependence.

Thus, Berry's (1966) work on Temne rice farmers in Sierra Leone and Eskimos in the Canadian Arctic, Dawson's (1967a, 1967b) research in West Africa (again, mainly Temne people), Witkin and his colleagues (1974) in the Netherlands, Mexico, and Italy, and others culminated in a synthesis that links ecology, culture, and psychological processes. Relative to those cultures that rely on subsistence-level farming, the hunter-gatherer cultures tend to be looser in enforcing norms, socialize children to become more self-reliant, and consequently promote field independence, encouraging individuals to be both perceptually and socially independent (Witkin & Berry, 1975). Berry (1976, 1979) further emphasized the cultural dynamics that result from cultural contacts, wherein the traditional ecology-culture complex interacts with typically industrialized, market economy driven, and formally educated Western cultural groups. In many ways, this research program anticipated the recent development in culture and cognition research (Kashima & Gelfand, 2012; Masuda, Russell, Li, & Lee, [Chapter 8](#), and Talhelm & Oishi, [Chapter 4](#), this volume).

Developmental Approach

A major research program emerged, which highlighted child development within a sociocultural milieu as a critical focus of research in culture and psychology. Within a theoretical framework akin to that of Kardiner and Linton, J. Whiting and Child (1953) developed their framework that links ecology, child-rearing practices, and adult personality and behavior. Although theirs was a model inspired by psychodynamics, it also took its theoretical ideas from Hull's learning theory on habit formation, reflecting the influence of Neal Miller and John Dollard's attempt to integrate psychoanalysis and learning theory (LeVine, 2010). The main method of their empirical test was systematic analyses of ethnographic data in the Human Relations Area Files (HRAF), which was envisioned by and compiled under the leadership of an anthropologist, William Murdoch (eHRAF is now available online at <http://hraf.yale.edu>). They would code numerous ethnographies from different cultures collected in the HRAF in terms of their diverse cultural practices (e.g., punitive or nurturing child rearing) and cultural ideas (e.g., malevolent or benevolent deity), and

correlate them across multiple cultures. For instance, Lambert, Triandis, and Wolf (1959) reported that cultural beliefs in malevolent supernatural beings tend to go with a punitive child-rearing style.

Whereas the HRAF enabled them to investigate relationships between the relevant variables across a number of cultural groups, the ethnographic data available at the time had been collected in the past, and not all relevant data could be brought to bear on the theory. Noting a large gap in the empirical data, John Whiting (anthropology), Irvin Child (psychology), and William Lambert (psychology) launched a massive effort to collect relevant data on socialization (LeVine, 2010), which later came to be known as the Six Cultures Study. Beatrice and John Whiting, and their colleagues (e.g., Minturn & Lambert, 1964; B. B. Whiting, 1963; B. B. Whiting & Whiting, 1975) examined a variety of child-rearing practices and their psychological correlates within their model of psychocultural research at six locations around the world: Taira, Okinawa, Japan; Tarong, Luzon, the Philippines; Khalapur, Uttar Pradesh, India; Nyansongo, Kenya; Juxtlahuaca, Oaxaca, Mexico; and Orchard Town, New England, the United States.

Looking back at Whiting and Whiting, and their colleagues' sustained effort to capture children's socialization in their sociocultural milieu, Edwards and Bloch (2010) listed as their key ideas (1) the assumption of the psychic unity of human kind, (2) the cultural learning environment, (3) the psychocultural model, (4) the synergistic relationship of the disciplines of psychology and anthropology, and (5) the role of mothers as agents of social change, and concluded that their legacy is well and alive in the contemporary research on culture and child development. What is perhaps most significant in the context of cultural psychology is their developmental approach to the mutual constitution of culture and psychology, and their attempt to capture the social and cultural context in which psychocultural ontogenesis occurs.

Cognitive Approach

If the ecological and developmental approaches are concerned with processes that are relatively far or a medium distance away from the culture–psychology nexus, the cognitive approach to culture and psychology is much

closer to home. While behaviorism dominated the mainstream psychology, some domains of inquiry retained strong interest in nonobservable mental processes. They included social psychology. With the influences of a large number of scholars, including Kurt Lewin (1890–1947), Fritz Heider (1896–1988), Solomon Asch (1907–1996), Carl Hovland (1912–1961), and Leon Festinger (1919–1989), social psychology as a subdiscipline of psychology retained a conceptual curiosity for cognition, especially in the form of the attitude concept and Gestalt psychology. In a sense, social psychology provided a niche in which cognitively oriented research in culture and psychology could survive.

One example is Osgood, Suci, and Tannenbaum's (1957) *The Measurement of Meaning*. Based on Osgood's associationist (and almost stimulus–response [S-R] behaviorist) theory of meaning, they developed a measurement technique, semantic differential, and examined connotative meanings of a variety of concepts. Noting that a concept has a denotative meaning (i.e., what the concept refers to), it has additional meaning that it connotes. It was factor analysis developed in psychology that provided a powerful data-analytic technique by which to extract and reduce the vast and complex connotations to a relatively simple three dimensions—evaluation, potency, and activity (EPA). In particular, the first of its dimensions, evaluation, mapped neatly on to the social-psychological concept of attitudes. Osgood, May, and Miron's (1975) *Cross-Cultural Universals of Affective Meaning* was a massive exercise to examine connotative meaning across 25 cultural groups. In the end, the first three dimensions turned out to be EPA; hence the claim of universality. Osgood suggests the universality of these dimensions reflect their evolutionary significance—whether an object is good or bad (evaluation) for the actor, and strong or weak (potency) and active or passive (activity) in relation to the actor.

Triandis and his colleagues' (Triandis, 1964, 1972, 1973; Triandis, Vassiliou, & Nassiakou, 1968) work on *subjective culture* developed concurrently with Osgood's research program. In the first article of the first volume of *Advances in Experimental Social Psychology*, Triandis (1964) reviewed the then current literature in the emerging field of cognitive psychology and began to develop a list of psychological constructs that seemed useful for psychological analyses about how people perceive their

social environment. Fundamental to Triandis's analysis was *categorizations*. Categories cognitively carve up the world into meaningful chunks. However, categories are related to each other in some way, and culture influences both categories and relationships among them. Based on this basic scheme, Triandis developed a set of psychological constructs eventually incorporated into his theory of interpersonal behavior (Triandis, 1977). They included the relationships between a category and evaluation *à la* Osgood (evaluation understood as a special set of categories), a category and a category of behaviors directed toward the category judged in terms of intention (behavioral intention) or appropriateness (behavioral norm) to perform the latter, and so on. Triandis et al. (1968) conducted a systematic cross-cultural comparison between the United States and Greece, and later expanded this line of research to other cultures such as India and Japan (Triandis, 1972).

This research program was an inductive attempt at a systematic description of cultural differences in how people cognized their social environment (i.e., who does what to whom). It yielded both culture-general and culture-specific insights into the cognitive representations about the social world. For instance, Triandis et al. (1968) found that, generally across cultures, the dimensions of evaluation and intimacy are critical for interpersonal behaviors. Yet, they noted that there is some cultural specificity, noting that a culturally available concept such as *amae* in Japanese may capture an *emic* (taken from *phonemic*) aspect of a culture. In particular, Triandis (1972) provided some interpretive ideas to make the largely descriptive data intelligible: In some cultures, one's group (ingroup) is much more sharply distinguished from other groups (outgroup), and one's self-concept may be more importantly defined by the ingroup's perception than by one's own perception, foreshadowing the later development in the research on individualism and collectivism, and independent and interdependent self-construal (Kashima & Gelfand, 2012).

Institutionalization of Cultural Research in Psychology

In the latter half of the 1960s and the early 1970s, a number of international conferences were held, and journals were established with an explicit intent to foster cross-cultural research in psychology. In January 1967, a conference

was held in Ibadan, Nigeria, under the program committee cochairmanship of M. Brewster Smith and Henri Tajfel, with Henri Tajfel's initiative and Herbert Kelman's leadership. Although Tajfel was unable to attend the conference, its attendees included Donald Campbell (United States), Henri Collomb (Senegal), Rogelio Diaz-Guerrero (Mexico), Gustav Jahoda (United Kingdom), Marshall Segal (United States), and Harry Triandis (United States), among others. The purpose was to foster collaboration among psychologists across the world, especially with a view toward contributing to the national development of less industrialized countries, including those in the sub-Saharan Africa (Kelman, 1968). In 1972, the first conference of the International Association for Cross-Cultural Psychology was held in Hong Kong, with Jerome Bruner as its first president. Publication of journals such as the *International Journal of Psychology* (1966), *Cross-Cultural Research* (1966), and the *Journal of Cross-Cultural Psychology* (1970) began, thus providing an outlet for culture-minded psychologists.

In 1980–1981, a six-volume *Handbook of Cross-Cultural Psychology* appeared, which compiled much of the culture-relevant research in psychology up to the 1970s. It contained not only the historical and theoretical background and methodology but also the substantial empirical research about cultural influences on basic psychological processes such as perception, cognition, and motivation, as well as child development, social behavior, and psychopathology. In particular, the methodological discussion and ethical consideration about cross-cultural research stand out (Kashima & Gelfand, 2012). For instance, extensively discussed was the enduring methodological question about whether a theoretical construct used in psychology is in fact doing justice to the culture to which it is applied. Just as pronunciations in a language may be described by a universal set of *phonetic* sounds but there is a set of “phonemes” (i.e., sounds that are unique to and meaningful in a linguistic community), Pike (1954) called universally applicable cultural constructs “etic,” but culturally specific constructs “emic.” Berry (1968) was concerned that what may be regarded as etic constructs and methodological tools based on these constructs may in fact be *imposed etic*—a researchers' own emic constructs masquerading as etic, or metaphorically trying to fit a square peg into a round hole. In addition, cross-cultural research ethics was tackled by a committee headed by June

Tapp. The report of Tapp, Kelman, Triandis, Wrightsman, and Coelho (1974) stands to this day as a first self-conscious effort to consider the ethicality of cross-cultural research.

THE EMERGENCE OF CULTURE AS A RESEARCH FOCUS

In the 1970s, world affairs outside of academia and theoretical and empirical developments inside the discipline of psychology began to set the scene for a sea change—questioning the natural science model of psychology and its Enlightenment worldview that goes with it. To begin, outside academia, a number of world events began to cast doubt on the Enlightenment grand narrative of progress. On the Western side of the Iron Curtain, the United States and its allies were involved in a prolonged warfare; because many of its citizens failed to see its legitimacy, student antiwar protests, the hippie movement, and a loosening of the traditional lifestyle went hand in hand, and the Vietnam War ended in the fall of Saigon and the defeat of the U.S.-backed South Vietnam in 1975. On the Eastern side, the economic decline of the Soviet Union and its Warsaw Pact allies became apparent despite the deepening Cold War. The Cultural Revolution in the People's Republic of China (1966–1976) was beginning to be seen not so much a progressive pathway toward a Maoist ideal society as a setback of its cause, as evidenced in its official denouncement in 1981.

Inside academia, scholars, including Clifford Geertz, Paul Ricoeur, and Charles Taylor, began to criticize the natural science model of human action and ushered in an “interpretive turn” that began to consider a cultural science model as a potentially viable alternative. In psychology proper, Kenneth Gergen and others launched a social constructionist movement and argued for the historically contingent nature of social-psychological knowledge. More generally, there was a discussion about Postmodernism (e.g., Lyotard, 1979/1984), according to which the Enlightenment grand narrative of progress that legitimized the knowledge and culture of modernity collapsed. Perhaps most symptomatically, Amos Tversky and Daniel Kahneman began their full-scale assault on human rationality, the hallmark of the Enlightenment conception of the person, by undermining

the belief that the human mind operates in a logically coherent manner—human reasoning was not rational after all! The irony of it all is that they used the trademark of the natural science model of psychology—axiomatic theory and experimental method—to challenge the very foundation of the Enlightenment ideology of universal human rationality.

In the meantime, the global economy began to expand and material prosperity was further extended, especially in North America, Western Europe, and East Asia. This was fueled in the 1980s by the transatlantic alliance between Margaret Thatcher (Prime Minister of the United Kingdom, 1979–1990) and Ronald Reagan (President of the United States, 1981–1989), so much so that some have announced “the End of History” (Fukuyama, 1992), or the Western capitalist democracy as a final form of human institutional development. With the increasing volume of exchange of not only capital, goods, and services but also people, the worldwide process of Globalization began to be apparent. Many business deals were made across national borders, business people began to travel to foreign countries, more citizens began to travel to distant parts of the world, and people began to be exposed to diverse cultural elements from the parts of the world that previously had been largely irrelevant to their lives.

It is symptomatic of the era that Geert Hofstede, who worked for a multinational company, produced one of the catalytic publications, *Culture's Consequences* (Hofstede, 1980). Using work values data from IBM employees from more than 40 countries around the world, he constructed four dimensions of culture: *power distance* (the extent to which power differences in hierarchy are tolerated), *individualism* (the extent to which individuals are separated from their organizational context), *masculinity* (the extent to which gender roles are differentiated), and *uncertainty avoidance* (the extent to which uncertainty is disliked and clear rules are preferred). Of these four, individualism was later to become a major focus of the research in culture and psychology. Hofstede's individualism and its opposite, collectivism, distantly echoed Ferdinand Tönnies's *Gesellschaft* and *Gemeinschaft*, or Emile Durkheim's organic and mechanical solidarity, which these founding fathers of social sciences used to characterize what they regarded as a sociocultural change of Western Europe from traditional communities to modern society. With this social change, the material wealth of Western Europe dramatically increased. Consistent with this, Hofstede's

index of individualism highly correlated with gross domestic product (GDP) per capita across countries.

If Hofstede's was an empirical inspiration for cross-cultural research, Shweder and Bourne's (1982; Shweder, 1984a) provided a theoretical framework and an intellectual allure for culture in psychology. Shweder and Bourne (1982) abstracted three prototypical explanations of cultural diversity: universalism, evolutionism, and relativism. In universalism, cultural differences are deemphasized, and similarities are highlighted; in evolutionism, cultural variants are placed along the ladder of evolution, with a normative model at the endpoint of development (e.g., propositional calculus as the endpoint of rational reasoning); and in relativism, cultural variations are all understood within their contexts as equally valid and reasonable. They then reported empirical evidence of cross-cultural differences in person description, while approvingly quoting Clifford Geertz's unforgettable description of the Western conception of the person (Geertz, 1975, p. 48):

The Western conception of the person as a bounded, unique, more or less integrated motivational and cognitive universe, a dynamic center of awareness, emotion, judgment, and action organized into a distinctive whole and set contrastively both against other such wholes and against a social and natural background is, however incorrigible it may seem to us, a rather peculiar idea within the context of the world's cultures.

Reporting some evidence of person descriptions from North America and India, they claimed that Indian descriptions contextualize a person by providing rich contexts in which the action takes place ("sociocentric organic"), while North American descriptions decontextualize a person by using personality trait terms ("egocentric reductionist"). Examining universalist, evolutionist, and relativist explanations of this phenomenon, Shweder and Bourne (1982) concluded in favor of a relativist interpretation of the phenomenon, suggesting that the Indian concrete contextualized person description can be understood as holism as a mode of thought.

Although Hofstede's (1980) and Shweder and Bourne's (1982) contributions differ greatly in their theoretical orientation, empirical database, and worldly practical implications, both pointed to the conceptualization about the individual person and the individual's relationship to his or her social context as a focal point of cultural differences. Together with the theoretical and empirical impetus, continuing

globalization and human curiosity about and a real need for knowledge about world cultures prepared a fertile ground for further research on culture and psychology.

CULTURAL PSYCHOLOGY AS A MOVEMENT

Beginning

On March 14, 1980, a number of notable anthropologists gathered at a conference at the University of California, San Diego. Those present included Roy D'Andrade, Clifford Geertz, Melford Spiro, Robert LeVine, Theodore Schwartz, and Richard Shweder. The conference's product, an edited volume, *Culture Theory*, was described by Shweder (1984b) as representing "a stage in the development of the so-called symbols-and-meanings conception of culture" (p. 1), quoting Geertz's (1973, p. 89) definition of culture as "an historically transmitted pattern of meanings embodied in symbols, a system of inherited conceptions expressed in symbolic form by means of which men communicate, perpetuate and develop their knowledge about and attitudes towards life." Clearly signaling the intellectual lineage to the Counter-Enlightenment tradition, Shweder (1984a) characterized this line of thinking as "anthropology's romantic rebellion against the enlightenment." Subsequently, in 1986 and 1987, the Committee on Human Development at the University of Chicago, with which Shweder was affiliated, hosted the Chicago Symposia on Human Development, culminating in the publication in 1990 of *Cultural Psychology*—arguably the beginning of cultural psychology as a self-conscious academic movement.

In it, Shweder (1990, p. 1) wrote, "A discipline is emerging called 'cultural psychology.' It is not general psychology. It is not cross-cultural psychology. It is not psychological anthropology. It is not ethnopsychology. It is cultural psychology. And its time may have arrived, once again." Shweder defined this emerging discipline as "the study of the way cultural traditions and social practices regulate, express, transform, and permute the human psyche, resulting less in psychic unity for humankind than in ethnic divergences in mind, self, and emotion. Cultural psychology is the study of

the ways . . . psyche and culture . . . require each other, and dynamically, dialectically, and jointly make each other up” (p. 1).

Shweder’s cultural psychology takes the view of humans as meaning-seeking and meaning-making beings who collectively constitute their *intentional world*. Intentionality in this context does not exclusively mean the notion of intention as in a person’s intention to do something, but rather a philosophical notion of intentionality, in which mental activities are said to be *about* something. Most of the mental verbs in English (e.g., “believe,” “want,” “intend”) take a propositional object. For instance, to say that “John believes it is raining” implies that John has a certain mental inclination toward the proposition that “It is raining.” More generally, the mind is said to have certain inclinations (often called “propositional attitudes”) toward a proposition about the world. These inclinations (e.g., believing, wanting, and intending) are the operations of the mind. According to Shweder (1990, p. 2), a sociocultural environment is an intentional world, because “its existence is real, factual, and forceful, but only as long as there exists a community of persons whose beliefs, desires, emotions, purposes, and other mental representations are directed at it, and are thereby influenced by it.”

As Shweder himself noted, this conception of cultural psychology tends toward relativism—there is no logical necessity that objects and events in one intentional world are the same in another. This is not to say that there are no universals. Indeed there may be, but they are not logically necessary in this perspective. Nonetheless, this conception rejects a view that there is no ontological reality—an intentional world is real, and psychological processes can operate within it rationally in the sense that they are internally coherent and consistent with the ontology of the intentional world. Shweder’s cultural psychology examines personal function, interpersonal maintenance of an intentional world, and psychosomatic, sociocultural, and divergent realities (Shweder, 1990, p. 3). Echoing Dilthey (1883/1988), he suggests that cultural psychology is an interdisciplinary *human science*.

A Variety of Cultural Psychologies

In parallel with this development, Jerome Bruner (1990) was conceiving a cultural psychology that also takes meaning seriously. His *Acts of Meaning*

was based on a series of lectures delivered at the Hebrew University of Jerusalem in December 1989. In the very first pages of this slender book, Bruner, one of the central figures of the Cognitive Revolution, wrote:

The Cognitive Revolution . . . was intended to bring “mind” back into the human sciences after a long cold winter of objectivism. . . . That revolution has been diverted into issues that are marginal to the impulse that brought it into being. . . . I want to turn directly to a preliminary exploration of a renewed cognitive revolution—a more interpretive approach to cognition concerned with “meaning-making.” (pp. 1-2)

Thus, Bruner’s cultural psychology also had intellectual roots in the Romantic tradition and the cultural science model of psychology. He suggests that folk psychology—culturally available concepts and naive theories used to understand and describe psychological states and processes (e.g., beliefs, desires, and intentions), and ideas and practices derived from or based on them—and narrative explanations of actions and events are fundamental to cultural constitution of the world. In his view, construction of narrative interpretations is a cultural achievement through phylogeny, history, and ontogeny, and is not only mediated by individuals’ cognitive activities but also is negotiated and renegotiated in social interactions with others. A result is the construction of a moral world in which one’s self is understood and constituted as a moral agent. The emphasis on narrative has inspired cultural research that examines the role of cultural narratives in maintaining cultural values and cultural stereotypes (e.g., Imada & Yussen, 2012; Lyons & Kashima, 2003).

It was also in 1990 that Michael Cole published an article, “Cultural Psychology: A Once and Future Discipline?” as part of the 1989 *Nebraska Symposium on Motivation*. Its content was expanded and further developed in a book with the same title minus the question mark (Cole, 1996). Cole is a cognitive psychologist, trained in mathematical learning theory. After conducting a field study in Liberia, however, he began to develop a research program on cognitive development informed by Vygotsky, Luria, and the Russian sociohistorical tradition of psychology. According to Cole, psychological processes are a product of phylogeny, cultural history, and ontogeny, and thus, evolution, history, and lifetime development through childhood, adulthood, and beyond. The distinctive characteristic of Cole’s cultural psychology is its tenacious focus on *context*. Recalling the Latin root of the word, *contexere*, which means “to weave together,” he approvingly

cited the *Oxford English Dictionary* definition of context as “the connected whole that gives coherence to its parts” (Cole, 1996, p. 135). To him, context is a complex whole that connects cultural artifacts, as well as culturally informed concrete practices and activities *in situ*. For instance, Chavajay and Rogoff (1999) videotaped children’s interactions with their caretakers and others in their homes, coded their patterns of attention to examine cultural differences in whether children would alternate their attention to different events that compete for their attention (i.e., looking at one thing, then the other) or pay attention to both at the same time, and found that Guatemalan Mayan children tended to engage in simultaneous attention more than did U.S. children from Salt Lake City, Utah. To be sure, psychological processes—both their mental and behavioral aspects—are inseparable from their concrete enactments, which are inevitably imbued with historically generated cultural meanings. Nevertheless, Cole’s cultural psychology is a study of situated artifacts–activities nexus thus construed.

Ernst Boesch’s (1991) *Symbolic Action Theory and Cultural Psychology* also deserves attention. Drawing on an action theoretical tradition of Kurt Lewin and others, Boesch characterized culture as

a field of action, whose contents range from objects made and used by human beings to institutions, ideas and myths. Being an action field, culture offers possibilities of, but by the same token stipulates conditions for, action; it circumscribes goals which can be reached by certain means, but establishes limits, too, for correct, possible and also deviant action. The relationship between the different material as well as ideational contents of the cultural field of action is a systemic one; i.e. transformations in one part of the system can have an impact in any other part. As an action field, culture not only induces and controls action, but is also continuously transformed by it; therefore, culture is as much a process as a structure. (p. 29)

Boesch’s *symbolic* action theory extends the action theoretical notion of action as goal-directed human activities in a field of activities, and takes the view that action has “connotations” or “symbolisms”—implied meanings that go beyond its denotation. Symbolic action is not only informed by culture but also transforms culture as it is performed. As Jahoda (1991) noted in his Foreword to Boesch’s book, it is his insistence on the dynamics of cultural meaning that places his cultural psychology broadly in the tradition of Dilthey’s human science.

Finally, it is important to note *indigenous psychologies* (e.g., U. Kim & Berry, 1993b; U. Kim, Yang, & Hwang, 2006) as an intellectual movement in

parallel to the variety of cultural psychologies described earlier. In the edited volume that bears the name of indigenous psychologies, U. Kim and Berry (1993a) defined the movement as “the scientific study of human behavior (or the mind) that is native, that is not transported from other regions, and that is designed for its people” (p. 2). Its prototypical operation is to use the concepts indigenous to a given culture to investigate the psychological processes of the people with that cultural background. The 1993 volume includes chapters by Durganand Singh on India, Rogelio Diaz-Guerrero on Mexico, James Georgas on Greece, Pawel Boski on Poland, Fathali Moghaddam on Iran, Virglio Enriquez on the Philippines, and David Ho on China, among others—they are investigations of each of the cultures by a well-known scholar indigenous to the culture. The initial aspiration of this intellectual movement shares many of its themes with other cultural psychologies. It endorses *a* scientific approach but shuns the Enlightenment conception of psychology as a natural science. Whereas it does not necessarily deny a cross-cultural comparative approach, its ultimate aim is to gain an understanding of and causal knowledge about the psychological processes within a cultural milieu. As Kashima and Gelfand (2012) noted, indigenous psychologies are indigenous to North America and Western Europe, indigenous psychology is indigenous to the rest of the world. Arguably, Nisbett and Cohen’s (1996) culture of honor is an intriguing example of indigenous psychology of the Southern United States.

Prehistory

The foregoing may seem to suggest that all these variants of cultural psychology sprang up all of a sudden around 1990. However, the term “cultural psychology” is not a neologism of the 1990s. Already in the 1960s, in the second edition of *Handbook of Social Psychology*, George DeVos (DeVos & Hippler, 1969), a psychological anthropologist of renown, wrote a chapter titled “Cultural Psychology: Comparative Studies of Human Behavior.” He wrote, “A distinct theoretical orientation variously called by anthropologists ‘personality and culture,’ ‘psychological anthropology,’ or ‘cultural psychology’ has evolved around a dual theoretical framework

applied to the study of human behavior as determined both by cultural and by personality variables” (p. 323).

DeVos began his extensive review with his reflection on the broad concepts of “culture” and “personality.” First, he cited Kroeber and Kluckhohn’s (1952, p. 181) well-known formulation:

Culture consists of patterns, explicit and implicit, of and for behavior, acquired and transmitted by symbols constituting the distinctive achievement of human groups, including their embodiment in artifacts; the essential core of culture consists of traditional (i.e., historically derived and selected) ideas and especially their attached values; culture systems may, on the one hand, be considered as products of action, on the other as conditioning elements of future action.

He then characterized “personality” as equally “broad in scope” (p. 324):

The same behavior viewed as a part of culture can also be considered in terms of a psychological structure deriving from man’s [*sic*] biological and physiological potentials and limitations. Personality “structures” are learned patterns dependent on a cultural environment, but they are no more reducible to analysis only in cultural terms than cultural patterns are reducible to psychological patterns. (p. 324)

Discernible from this passage is DeVos’s broad understanding of “personality” as including all spectrums of psychology from physiological through perceptual and cognitive to developmental personality and social psychology. In line with his broad definition, his review touches on all these aspects of the then-current research on cultural influences on psychology. Cultural psychology, as described by DeVos, was meant to cover the entire terrain of psychology as it intersects with culture.

Nonetheless, it was in the nexus of culture and “personality” more narrowly conceived that the next chapter of prehistory of cultural psychology as an academic movement began to unfold. A flagbearer of the Cognitive Revolution from anthropology, Roy D’Andrade (1965) challenged the trait conception of personality: “One of the hazards of science is the ease with which it is possible to confuse propositions about the world with propositions about language. Such a confusion appears to have occurred with respect to personality and behavior classifications in the field of psychology” (p. 215). This coincided with Mulaik’s (1964) self-criticism of trait psychology within the discipline of psychology itself, pointing to the possibility that what appears to be a coherent pattern of behavior attributable to a person (e.g., extraverted behaviors) may in fact be more a

reflection of conceptual structure (i.e., extraversion) than a reflection of the structure of behaviors.

There emerged in this academic climate the person–situation debate in personality and social psychology. To put it simply, the debate may be framed in terms of two questions: Is there a coherent pattern of behavior that is stable across different situations, or is someone’s behavior largely determined by the situation in which it occurs? Against the traditional assumption of personality psychology, a personality psychologist, Walter Mischel (1968) took a strong stance on the side of situationism, challenging the existence of stable personality. If there is no cross-situationally stable behavioral pattern in an individual, where does “personality” exist? Does it exist only in “the eyes of the beholder” (Cantor & Mischel, 1977)? At about the same time, an individual person’s psychological coherence began to be conceptualized in cognitive terms, as in Markus’s (1977) self-schema. Is it cognition that gives an individual person the appearance of possessing coherent personality? This line of reasoning was further extended in light of the then-developing literature on Tversky and Kahneman’s heuristic reasoning and human judgmental biases that cast doubt on human rationality. Some social psychologists (e.g., Ross, 1977) reduced the attribution of an individual’s behavior to a stable personality disposition to a “fundamental attribution error,” suggesting that it is a grave error to see a stable disposition in a human individual. Nisbett and Ross’s (1980) *Human Inference* captured much of the research in this vein.

Against this backdrop, Shweder published a series of essays that set a scene for the subsequent development of cultural psychology. In 1975, a paper appeared in the *Journal of Personality*. It revisited preexisting data from previous psychological studies, drawing on the then-current literature on judgmental heuristics and cognitive biases *à la* Kahneman, Tversky, and others, and providing support for D’Andrade’s (1965) suggestion that cognitive conceptual structures underlie much of the assumed coherence in personality, and that the concepts represented by personality trait terms such as “extraversion” and “introversion” may be biasing personality ratings and behavior observations. It was followed by an article in *Current Anthropology* (Shweder, 1977), and a three-part series in *Ethos*, a journal dedicated to psychological anthropology, which provided a critical reflection on the literature on culture and personality (Shweder, 1979a, 1979b, 1980).

In the last essay of this series, Shweder (1980) drew on Popper's notion of World 3 (Popper & Eccles, 1977) to justify his view that meaning—or products of the human mind, particularly rules that regulate human conduct—constitutes a domain separable from the worlds of the objective things and events (World 1) and the subjective psychological state (World 2). This conceptualization connects to the view of cultural psychology as a study of intentional world, which he later espoused in 1990.

The Standard Theory of Cultural Psychology

On both sides of 1990, when Stigler et al.'s *Cultural Psychology* was published, two articles appeared in *Psychological Review*: Harry Triandis's (1989) "The Self and Social Behavior in Differing Cultural Contexts" and Hazel Markus and Shinobu Kitayama's (1991) "Culture and the Self: Implications for Cognition, Emotion, and Motivation," both focusing on the psychological construct of *self* and its implications for culture and social psychology. Ten years later, Nisbett, Peng, Choi, and Norenzayan's (2001) "Culture and Systems of Thought: Holistic versus Analytic Cognition" also appeared in *Psychological Review*, extending the discussion about cultural variability to cognition more generally. It seems fair to say that these three articles together constructed a platform from which many of the contemporary contributions in culture and psychology were launched.

Triandis (1989), drew a distinction between the cultural and psychological levels of analysis by suggesting that "culture is to society what memory is to the person" (p. 511). Starting with the importance of ecology as a distal cause of cultural variability, he highlighted three dimensions that capture cultural variations—cultural complexity, individualism–collectivism, and tight–loose cultures—and three types of self-concept—private, public, and collective self, and theorized relationships between cultural dimension and the likelihood with which these different self-concepts are activated to influence social behavior. Broad cultural differences dictate the types of self-concepts prevalent in culture, and situational differences make different self-cognitions salient. Markus and Kitayama (1991), while acknowledging a universal aspect of self-cognition, drew an elegant distinction between two types of self-construal,

independent and interdependent, as the extent to which people “see themselves as *separate* from others or as *connected* with others” (p. 226; emphasis in the original). They explicated these two types of self-construal and reviewed the then-available research on cultural differences in self-construal and their psychological implications in terms of cognition, emotion, and behavior. Thus, authors of these two articles theorized about three classes of psychological constructs—culture, self, and psychological processes—and hypothesized potential relations among them.

Nisbett et al. (2001) theorized that cognition is fundamentally embedded in social organization of everyday life. To the extent that culture and self shape ways of life and humans relate to each other, they, too, should shape cognition. In particular, they argued, social organization and social practices that go with it direct selective attention, which influences beliefs about the nature of the world and causality (metaphysics), which in turn guides beliefs about what to know and how to know (epistemology), with these beliefs dictating the development and application of cognitive processes. Drawing a broad distinction between holistic and analytic cognition, they argued that social organization and practices characterized by independence and separation (vs. interdependence and connectedness) between individual persons tend to promote analytical (vs. holistic) cognition, which separates an object of construal from its background (vs. embeds an object of construal within its field).

In retrospect, the three articles pivoted around the main theme that has been variously called individualism–collectivism, independence–interdependence, and analyticism–holism, which all find their conceptual ancestors, as noted earlier, in various past writings in culture and psychology in particular, and social sciences more broadly. What is remarkable is that these threads of theoretical lineages converged at the rich conceptual nexus of the self and causal attribution research in personality and social psychology. They collectively hinted at the significant analytical distinction among culture, social organization, and psychology; sharply directed researchers’ attention to the individual in social context; to the domain particularly rich with meaning, history, and intellectual implications beyond personality and social psychology narrowly conceived; and directly and indirectly addressed the growing need for a broad framework to aid cross-cultural understanding, especially between the West and the rapidly

developing East Asia, in the globalizing world. In so doing, they provided a generative conceptual apparatus for empirical research.

Postscript

The rhetoric to differentiate cultural psychology in opposition to other traditions of research in psychology enabled a clear focus and rallying point for culture-relevant psychological research. Research at the intersection of culture and psychology significantly increased in quantity and scope. While academic journals in psychology with cultural emphases continued to be published, in some cases with more issues per year, new journals with cultural themes, *Culture and Psychology* (1995) and *Asian Journal of Social Psychology* (1998; published by the Asian Association of Social Psychology, founded in 1995), began to appear. All in all, since 1990 or so, the publications that include “culture” or “cultural” as a keyword increased rapidly and have nearly doubled by now (2015) from about 5 to 10% of the total publications in psychology included in PsycINFO (Kashima, 2016). In addition, going beyond the narrow East—West comparison of individualism and collectivism or independent and interdependent self-construal, cultural research in psychology has begun to include much greater geographical areas—Latin America, the Middle East, and South Asia—and cultural phenomena—religion, socioeconomic status, and others—as covered in this second edition of the *Handbook of Cultural Psychology*.

However, the explosion of research in the nexus of culture and psychology prompted further soul searching and self-reflection among researchers. Recall that Shweder distinguished cultural psychology from cross-cultural psychology; the indigenous psychology movement claimed its distinctiveness from both as a research orientation of the people, by the people, and for the people who share a cultural background. Debates and discussions about similarities and differences between research perspectives began to take shape. A concrete instance of this took place at the third conference of the Asian Association of Social Psychology, in Taipei, Taiwan, August 4–7, 1999. Scholars representing three perspectives were brought together: Richard Shweder and Patricia Greenfield for cultural psychology, Harry Triandis and John Berry for cross-cultural psychology, and Kuo-shu

Yang and Uichol Kim for indigenous psychology. Further adding an article by Sik Hung Ng and James Liu (2000), Kwang-Kuo Hwang and Chung-Fang Yang guest-edited a special issue of the *Asian Journal of Social Psychology* (2000) that included seven articles, presenting seven distinct, sometimes complementary, and at times antagonistic perspectives on the three approaches. The turn of the century was a vibrant time for culture and psychology.

EMERGING CONSENSUS IN CONCEPTION OF THE PERSON IN PSYCHOLOGY

Even if the tension between the Enlightenment and Romantic conceptions of the person has driven the dynamics of the natural science and cultural science models of psychology in the 20th century, toward its *fin de siècle*, the methodological tensions between the natural and cultural science models (e.g., see what Cohen, Nisbett, Bowdle, & Schwarz [1996] called experimental ethnography), as well as metatheoretical tensions (see what Kashima & Haslam, [2007–2008] called experimental semiotics) began to ease, and it is possible to see an emerging consensus in how psychologists came to see what it means to be human (Kashima, 2000a). It is characterized by four fundamental assumptions: ontological physicalism, Darwinian evolutionism, cultural ontogenesis, and mind–culture constitutionism.

First of all, the question about the nature of the mind—whether it consists of material matter just like any other physical things and events in the world or a “mind” matter that is fundamentally different from the material—seemed to have become obsolete. Few psychologists, if any, were seriously asking this question, and most took it for granted that physical matter, by its material composition and complex organization, gives rise to the phenomenon of the mind. It is the physical brain—and the brain is not in a vat, but there is the body to go with it!—that does the thinking, feeling, and wanting. In a way, this ontological question seems to have been an implicit underlying layer for the metatheoretical question about how to conceptualize psychological processes and the nature of cognition, and the methodological question about how to investigate them—causal explanation or hermeneutic interpretation. If the mind is made up of mind matter and

the rest of the world is made up of material matter, it makes sense to approach them differently, by different methods. However, if cognition—and interpretation is obviously an instance of cognition—is understood as a physical process, there is no reason why interpretation itself cannot be causally explained. Thus, the physicalist ontology took much of the vexation from the methodological question.

Second, the “grand synthesis” of Darwinian evolution and Mendelian genetics became a taken-for-granted assumption of the phylogenetic origin of humanity, and the view that culture is a species-typical property of *Homo sapiens* came to be taken seriously. That is to say, DNA-coded genetic information is passed along from parents to their offspring; blind variation and selective retention of this genetic information have cumulatively generated *Homo sapiens* as a biological species; and their genetic makeup enables humans to acquire and transmit culture. Thus, in the case of human beings, genetic information presupposes cultural information. In this sense, the human is a *cultural animal*.

Third, human ontogenesis is necessarily a process of enculturation. That is to say, human newborns are endowed with a brain and body that are not only receptive to cultural input but also presume it. The newborn without cultural input is incomplete at best; human adults are also endowed with a brain and body that inclines them to teach. Cultural information travels not only from parents to their genetic offspring but also from other adults to children, from other children to children, or even from children to adults (see how youngsters teach older adults how to use Facebook and Twitter!). Thus, the generation, transmission, and retention of cultural information, while interacting with conspecifics throughout the lifespan, are natural parts of human development.

Fourth, cultural–historical context and the human mind are mutually constitutive. As humans, with their genetically endowed brains and bodies, interact with each other in their everyday lives, they construct cultural context partly by design and partly by unintended consequences of their actions, and the cultural context cumulatively forms human history over time; thus, constructed cultural–historical contexts further make up the human mind for their future activities. Human psychological processes and cultural–historical processes are inexorably interwoven with each other to constitute human history and ways of life.

Toward Naturalization of Culture

The emerging consensus diverges from the Enlightenment–Romantic opposition. Recall that natural science and cultural science models of psychology both presupposed a nature–culture separation: Culture is either an add-on to the universal machinery, which can be safely ignored in an investigation of the mind for the natural science model, or a domain that has a life of its own, independent of the brain–body machinery of the cultural science model. In contrast, in contemporary discourse, culture is not only ontologically and phylogenetically enabled by nature, but it also ontogenetically and historically influences nature. Human beings are cultural by nature, and human nature includes culture as its integral aspect. Nature and culture are no longer separated in this conception of the person; they are interwoven with each other in the ever-changing temporal dynamics of human evolution, history, lifespan development, and situated sociality. In short, the new conception of the person takes nature, culture, and time very seriously indeed (Kashima, 2000a), thus the emphasis on *cultural dynamics* (Kashima, 2008, 2014) and an inclination to *naturalize culture* (Kashima, 2016).

This trend is aligned with an increasing emphasis on both nature and nurture in psychology, together with a growing recognition of epigenesis. Its reflection in cultural psychology is perhaps most discernible in the variety of ways in which theoretical concepts and research methods from biology have been brought to bear on the culture–mind nexus.

- *Gene–culture coevolutionism*. Darwinian mechanisms may be used to explain cultural evolution, which in turn affects genetic evolution (e.g., Boyd & Richerson, 1985; Cavalli-Sforza & Feldman, 1981; Mesoudi, [Chapter 5](#), this volume).

- *Cultural evolutionary account of religion*. Although religions have been considered a quintessential cultural element that defies scientific investigation, recent approaches regard religion as a cultural solution to the evolutionary problem of human cooperation (e.g., Atran & Norenzayan, 2004; Boyer, 2001; Norenzayan & Shariff, 2008).

- *Embodied culture*. Culture is not just abstract, disembodied representations or “the brain in the vat”; it is embodied and practiced (e.g.,

Cohen, Hoshino-Browne, & Leung, 2007).

- *Cultural neuroscience.* Use of neuroscientific methods such as electroencephalography (EEG) and functional magnetic resonance imaging (fMRI) may shed light on cultural influences on psychological processes (e.g., Chen, Burton, Greenberger, & Dmitrieva, 1999; Chiao & Blizinsky, 2010; Han & Humphreys, 2016; Y. Kim, Chiu, Peng, Cai, & Tov, 2010) and the genetic makeup of individuals may explain the outcome of culture learning (e.g., Han & Northoff, 2008; Kim & Lawrie, [Chapter 10](#), this volume; Kitayama, King, Hsu, & Liberzon, 2016; Kitayama & Uskul, 2011; Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume).

- *Cultural adaptationism.* The natural environment significantly shapes cultures, because cultures represent an adaptation to both environmental threats (e.g., Gelfand et al., 2011; Van de Vliert, 2008, 2013), including pathogen threats (e.g., Fincher, Thornhill, Murray, & Schaller, 2008), and the economic system for extracting resources from the natural environment (e.g., Talhelm et al., 2014; Talhelm & Oishi, [Chapter 4](#), this volume; Uskul, Kitayama, & Nisbett, 2008).

Naturalization of culture is most obviously discernible in niche constructionism in evolutionary biology (e.g., Laland, Odling-Smee, & Myles, 2010; Odling-Smee, Laland, & Feldman, 2003). In this view, organisms do not directly adapt to the natural environment, but construct their niche that enables them to adapt to the natural environment. A niche is like a beaver's dam—a beaver constructs its nest as part of the dam that it creates, and it is well adapted to survive in this beaver-constructed environment, which in turn almost seamlessly intermeshes with the rest of nature. Likewise, humans construct their own niches in the form of the built environment supported by the human-made production, distribution, consumption, and waste disposal system of goods and services, supported by the financial, educational, social, and other institutional arrangements. Thus, created human-made environments have structures and dynamics largely of their own (see Cohen, 2001); human minds adapt to these niches. Humans adapt to the natural environment not only directly but also indirectly through the culture-imbued, human-made environment. It is through the double loops of adaptation—one with the human-made environment and the other with the natural environment, which

intermeshes with the former—that human evolution takes place. The construction of these human niches obviously implicates cultural processes. In this way, culture is integral to evolution in niche constructionism.

These developments in academic research naturalized culture, but events outside the academia also began to fuel a need to naturalize the culture concept (Kashima, 2016). In 2001, two events ushered in a volatile period of human history. One was the September 11 attack on the World Trade Center in New York City. Two hijacked airplanes were crashed into a symbol of global capitalism by al-Qaeda-inspired individuals who apparently justified the deed with their religious beliefs. It signaled an increasing likelihood of intergroup conflicts along the religious lines that we witness today. The other was the third assessment of the Intergovernmental Panel on Climate Change (IPCC, 2001), a world body of climate scientists who provide periodical reports of the state of the climate on the Earth. It is the latter that is much less attention grabbing but potentially even more threatening to humanity than the former.

The IPCC warned that the global average temperature has increased over the past 200 years relative to the long-term average temperature during the geological epoch known as the Holocene. Since the Industrial Revolution, by burning fossil fuels such as coal and oil, the human production and consumption of goods and services have generated much more greenhouse gases (e.g., CO₂) than before. When trapped in the atmosphere, these gases increase the temperature on the planet, thus affecting the climate. Some have argued that given the disproportionate impact human activities now have, geology has entered a new epoch that should be prefixed by humanity, that is, the Anthropocene (e.g., Crutzen, 2002). In a way, this is human niche construction gone awry (Kashima, 2016). The amount of material goods and energy that humans' culture-imbued activities now harness is so large that it inevitably affects the biosphere of the planet (IPCC, 2007, 2014) without so intending. This realization—although there are some lingering debates about the veracity, extent, and consequences of climate change—has reminded humanity (and psychologists, I might add) of the need to take nature seriously in conceptualizing culture and the culture-imbued human mind.

Climate change can further amplify the intergroup conflict that the 9/11 attacks so dramatically symbolized. Climate variability has been known to worsen human violence and intergroup conflict—when the temperature deviates from the local long-term average, it tends to increase conflicts (for a meta-analysis of the relation between climate and conflict, see Hsiang, Burke, & Miguel, 2013). Apart from the direct impact of climate change, extreme weather events (e.g., hurricanes, floods, droughts, large-scale fires) deplete the economic and social resources within communities, and resource scarcities can further exacerbate conflicts of interest between human groupings (e.g., Zhang, Brecke, Lee, He, & Zhang, 2007). Climate change and human conflict can go hand in hand, further underlining the need to take nature seriously in the cultural dynamics of the 21st century and beyond.

CONCLUDING COMMENTS

Cultural psychology started as a tradition that takes *meaning* seriously; cultural psychology as a movement revived it around the 1990s. While natural science models dominated mainstream psychology, thin threads of research traditions kept alive various cultural science models at the periphery of psychology or in the liminal region of psychology and other human science disciplines. These diverse threads of theoretical ideas and methodological innovations began to converge in personality and social psychology in the late 1970s and 1980s. It was a confluence of theoretical developments in psychology—cognitivism, heuristics and biases in judgment and choice, meaning-rich research in personality and social psychology—as well as world events outside psychology—the end of the Cold War, advances in information technology, deepening globalization—that cast doubt on the research agenda of natural science models and highlighted a need for greater understanding of human diversity and cultural meaning. These historical trends came to a head, and their most visible events took shape in the form of academic activities and products such as workshops and conferences, as well as the publication of books and articles.

Here, it is the researchers—often trained in the institutionalized academic discipline of psychology, but very frequently in anthropology or even biology—who carry out these academic activities and produce these products we can now access in the historical archival records. It goes without saying that these are embodied people who live their lives in their own cultural and hisotorical context, enabled by the societal, economic, and governance apparatuses. Their thoughts, feelings, and actions are obviously shaped by the ongoing events in the world. I hope this chapter has illustrated that despite all the powerful events and happenings that affect the ever-changing fields of culture and psychology, these researchers’ sometimes explicit, but often tacit conceptions of the person—their ontology of what the person is and what it means to be human—at least in part drive their research activities, and it is researchers’ conceptions of the person that define their perspectives, approaches, and, in many ways, their outcomes and future potentialities for psychology (Kashima, 2000a, 2016; Smith, 1991).

Conceptions of the person were once divided between natural science and cultural science models, which both tacitly presupposed the ontological division between nature and culture. In my view, the currently emerging conceptions of the person no longer take this ontology, but locate culture as integral to human nature. Clifford Geertz (2000), a champion of the cultural science model, once warned that bringing culture into psychology would cause “a fair amount of noise and upheaval” (p. 196) and “do more to toss things around than to arrange them in order” (p. 197). If one’s conception of the person presupposes the nature–culture separation, this warning makes perfect sense—water and oil don’t mix, and natural scientific psychology would not mix with a cultural scientific psychology. As far as I can tell, however, an upheaval has not eventuated—at least not yet. Perhaps part of the reason is the emerging conception of the person that naturalizes culture. As a tradition and a movement, cultural psychology takes the meaning as a focal point of investigation. It is a definitional character of cultural psychology, and its retention is critical. However, at the same time, it needs to consider the implication of culture for human psychology in nature. How we conceptualize culture *in* nature, rather than culture *versus* nature, may point our way into the uncharted waters that are our common future.

ACKNOWLEDGMENT

Preparation of this chapter was facilitated by grants to Yoshihisa Kashima from the Australian Research Council (Nos. DP130100845 and DP130102229).

CHAPTER 3

Cultural Neuroscience

**Shinobu Kitayama, Michael E. W. Varnum, and
Cristina E. Salvador**

The field of cultural neuroscience seeks to understand how key features of culture, including beliefs, values, and practices, may get embrained and embodied in neurobiological systems through socialization. In so doing, it aims to investigate how deep the influence of culture may go in making neurobiological systems closely attuned to the surrounding environment. In this chapter, we provide an overview of this new field of research. First, we discuss known cross-cultural variations in self, cognition, emotion, and motivation as revealed in brain responses. Second, we examine how culture may interact with biological processes more generally by discussing recent work on (1) gene × culture interactions and (2) links between culture and biological health. Our overarching goal is to elucidate how the neuroscience approach has helped address questions that are difficult to answer with existing behavioral and self-report measures alone. We conclude by highlighting directions for future research.

Cultural neuroscience is a young and vibrant field of research that is only 10 or so years old. The first publication bearing the name “cultural neuroscience” appeared in the first edition of this handbook (Chiao & Ambady, 2007). Since then, the number of publications in this field has increased exponentially. Major workshops have regularly been held in various venues around the globe. An independent handbook has been compiled for the field (Chiao, Li, Seligman, & Turner, 2016). Research articles have frequently been published in top outlets, including *Proceedings of National Academy of Sciences USA*, *Psychological Science*, *Perspectives on*

Psychological Science, Emotion, Social, Cognitive, and Affective Neuroscience, and NeuroImage, just to name a few. As a testament to the growing importance of cultural neuroscience, the *Annual Review of Psychology* recently featured three articles on this topic over the span of 4 years (Han et al., 2013; Kim & Sasaki, 2014; Kitayama & Uskul, 2011). In addition, a journal singularly devoted to the field (*Culture and Brain*) has been established. Despite its young age as a field, the contributions of cultural neuroscience have been numerous and are likely to grow.

WHAT IS CULTURAL NEUROSCIENCE?

The primary aim of cultural neuroscience is to investigate how deeply culture, including beliefs, values, and practices, may go “under the skin”; that is, the field aims to understand how key features of culture practiced over time, through socialization, may influence biological systems composed of both brain and body to attune individuals to their environment (Han et al., 2013; Kitayama & Uskul, 2011). An important first step in accomplishing this broad aim was to establish differences between sociocultural groups in brain mechanisms underlying various psychological functions. The next step is to begin to shed light on how the effects of culture on the brain might have come about. Yet another step would be to investigate similar cultural effects in other biological systems, including genetics, epigenetics, and biological health.

Through this effort, the cultural neuroscience approach has provided some empirical substance for a time-honored argument by George Mead, Pierre Bourdieu, Anthony Giddens, and other early social scientists. These scholars argued that the body (and now the brain as well) is closely attuned to the sociocultural environment, while at the same time (since the attunement to the environment is not complete) the body–brain that is conditioned to the surrounding environment can simultaneously be autonomous, thereby constituting agency, being capable of producing volitional actions, which can lead to changes in the environment from which the agency has been derived. This circular or recursive process occurs continuously, not only in each person’s lifetime but also across generations,

hence eventually giving rise to changes in both historical and evolutionary timescales.

In the last decade, many researchers have contributed to the agenda of cultural neuroscience by investigating neurophysiological mechanisms of cultural influence in various substantive domains. They include perceptual processing (Goh et al., 2004), attention (Goto, Ando, Huang, Yee, & Lewis, 2010), the self (Han & Ma, 2014; Knyazev, Savostyanov, Volf, Liou, & Bocharov, 2012; Zhu, Zhang, Fan, & Han, 2007), social cognition (Knyazev, Savostyanov, Bocharov, & Merkulova, 2018), emotional experience (Immordino-Yang, 2014; Murata, Moser, & Kitayama, 2013; B. Park, Tsai, Chim, Blevins, & Knutson, 2016), perception of others' emotions (Goto, Yee, Lowenberg, & Lewis, 2013; Russell, Masuda, Hioki, & Singhal, 2015), empathy (Cheon et al., 2011), moral decision making (Han, Glover, & Jeong, 2014), norm violation detection (Mu, Kitayama, Han, & Gelfand, 2015), reward processing (Varnum, Shi, Chen, Qiu, & Han, 2014), and motivation (Kitayama & Park, 2014). Most of these studies focus on patterns of functional activation of the brain with methods such as functional magnetic resonance imaging (fMRI) and electroencephalography (EEG). However, an emerging line of work has examined cultural influences on other biological indices such as structural properties of the brain (Kitayama et al., 2017b; F. Wang, Peng, Chechlacz, Humphreys, & Sui, 2017), as well as markers of biological health and well-being (Kitayama & Park, 2017; Miyamoto et al., 2013). Furthermore, there is increasing interest in including biological and genetic evolution within the purview of the field (Kim & Sasaki, 2014; Kitayama et al., 2014).

The range of phenomena that are being explored cross-culturally with neuroscience methods is already vast, with a rapidly growing empirical base. In this chapter, we document how this relatively new approach in cultural psychology has made significant contributions that go beyond what was already known in the field. By doing so, we explicate how the neuroscience approach has enriched psychological theories of culture and, correspondingly, why this approach is invaluable for a better understanding of the dynamic interaction or mutual constitution between culture and the psyche (Markus & Hamedani, [Chapter 1](#), this volume; Markus & Kitayama, 2010). Indeed, this approach may even be indispensable for achieving the overarching agenda of cultural psychology.

In what follows, we present a review of the budding field of cultural neuroscience. We do so in three steps. First, we discuss what the neuroscience approach offers in the study of culture. Second, we consider available evidence on cultural variations in brain responses in several domains, including self, cognition, emotion, and motivation. We also consider emerging work on culture and the regionally specific cortical volume of the brain. Third, we turn to the role of culture in regulating broader biological systems, with a focus on two areas, namely, gene \times culture interactions and biological health. We conclude by drawing attention to current limitations and future opportunities for the field.

WHY NEUROSCIENCE?

“Culture,” defined as a pattern of beliefs, values, and practices that constitute one’s environment, may be studied with interviews or surveys. It can be studied by analysis of cultural products and archival data. It is also possible to study it with a variety of behavioral experiments. It is therefore legitimate to raise this question: Why neuroscience? Why is it that we may want to expend extra labor, time, and substantial financial resources to use neuroscience to study culture?

In this section, we discuss several reasons why the neuroscience approach is not only useful but also indispensable for advancing our understanding of how culture influences the human mind. We consider what theoretical gains we can expect with this approach and explain why we may want to take the extra labor and time to utilize neural measures. We do so by highlighting concrete examples that illustrate the benefits of the neuroscience approach in research on culture.

Psychological Mechanisms

At the most concrete and tangible level, cultural neuroscience has enabled researchers to more directly tap into the psychological mechanisms that mediate cultural influences in various domains. By doing so, it has helped

resolve earlier debates that were based solely on behavioral or self-report data.

For example, East Asians are known to report lower self-esteem than do European Americans (Heine, Lehman, Markus, & Kitayama, 1999). One possible interpretation of this cultural difference is based on tactical self-presentation. It might be the case that East Asians say they are not as high in self-esteem because of a strong modesty norm. That is to say, at heart, they may have views of the self that are as positive as Westerners' views, but they may intentionally hide their high self-esteem, because showing it is socially inappropriate. An alternative interpretation is that these cultural differences in self-report may reflect real internal differences. For example, there might be cultural differences in automatic tendencies to pay attention to negative (vs. positive) self-relevant information; that is, East Asians might appear to be modest in the eyes of outside observers because of their tendency to attend initially to potentially negative aspects of themselves. Since behavioral measures (e.g., in self-report, judgment, and memory, among others) necessarily tap downstream consequences only, it is both important and informative to directly probe the mediating psychological mechanisms by using neuroscience measures such as fMRI and EEG. Only by so doing can we address the initial question of genuineness in Asian modesty or the lack thereof. As we shall see, recent neuroscience investigations have favored the second account of this cultural difference.

The theoretical benefit of the neuroscience approach is not limited to the study of self-enhancement and self-criticism. The same is true in cognition, where research has shown that the fundamental attribution error (the bias to use dispositional reasons to explain another person's behavior) is cross-culturally variable. Furthermore, this cross-cultural variation is due to automatic, early cognitive processing rather than later, more deliberate cognitive effects. It also applies to dissonance and other related motivational phenomena, which are now known to stem from a conflict detection system of the brain that is closely modulated by cultural conditioning. In this chapter, we provide a selective review of cases in which this type of specification of underlying mechanisms has been accomplished through the use of neural measures.

Biological Plasticity

The effort to clarify the mechanisms behind cultural differences has led to a broader theoretical realization that some seemingly rudimentary psychological mechanisms, such as attention and information seeking, are plastically shaped and modified by culture. Cultural neuroscience work has therefore challenged a long-standing assumption that the psychological system is analogous to a computer, being both fixed and pancultural. In this traditional view, cultural variations may be explained by assuming that people in different cultures use different software that handles different inputs and produces different outputs. In this view, however, the core of the mind, the hardware (or the central processing unit; Shweder & Sullivan, 1990), is fixed and invariant across cultures. This assumption was at the base of the “cognitive revolution” of the 1950s. It was argued that if the computer can be studied and analyzed with science, why can't the mind? This reasoning was used to legitimate the mind as a target of scientific investigation. Moreover, this computer-based view of the human mind has since undergirded many theories in various subdisciplines of psychology, including cognitive psychology, social cognition, and developmental psychology.

Keep in mind that cultural variations of various beliefs and behaviors can be explained without challenging the putative reality of the universal, fixed, computer-like mind. One may hypothesize, for example, that input to this fixed mind is systematically different across cultures (Berry, Poortinga, & Pandey, 1980). It would seem reasonable that with different inputs, the system will spit out varying outputs (e.g., beliefs and behaviors). Following this logic, as long as this explanatory scheme is sufficient to account for known phenomena, there is nothing in cultural psychology that would challenge the standard model of the mind as fixed and universal. Research on culture could comfortably sit within the framework laid out by the central assumptions of the cognitive revolution.

Cultural neuroscience has seriously challenged these assumptions. It has done so by providing evidence that cultural influences go deep. Indeed, it is now clear that significant components of the putative universal mind are demonstrably shaped and modified by culture. By showing that biological and neural mechanisms that underpin mental activity are plastic and

constantly influenced by culture, cultural neuroscience has challenged the fundamental premise of many of the social and behavioral sciences.

Cultural neuroscience's challenge to the computer model was not without precedent. In fact, one central impetus for it came from recent evidence from other fields documenting extensive neuroplasticity in humans. For example, a pioneering study tested London cab drivers, whose work required driving through and learning the layout of a large, geographically complicated city at a time when computer-based navigation systems had yet to be widely adopted (Maguire & Gadian, 2000). Among these cab drivers, the area of the brain known to be implicated in spatial navigation and memory (the posterior hippocampi) increased in volume as a function of the years of experience driving a cab, despite the fact this area typically decreases in size with age. Likewise, a study focusing on Buddhist monks indicated that the high-frequency brain wave called the gamma (typically associated with active engagement of thought processes) becomes dominant during meditation and, moreover, is more prominent as a function of the years of meditation experience (Lutz, Greischar, Rawlings, Ricard, & Davidson, 2004). The preponderance of the gamma wave may reflect certain structural properties of the brain (although this point has yet to be tested). Accordingly, these demonstrations hinted at the possibility that hard structures of the brain undergo significant changes as a function of extensive experience.

These studies extend previous work with nonhuman animals that underscores the significance of experience in the plasticity of both neural connectivity and the structural volume of relevant brain regions. Building on this work, cultural neuroscience research has begun to show that culture in fact constitutes an external environment that "trains" the brain. Thus, when the brains of two people who have been trained in different cultural contexts are compared, they tend to show neural effects that correspond to key features of their contexts. This work has led to new questions regarding how environmental factors might result in structural changes in the brain (Kitayama et al., 2017b). Furthermore, such structural changes of the brain are likely to be mediated by epigenetic mechanisms (Cole, 2014; Meaney, 2001). This line of inquiry may begin to highlight cultural influences at this neurobiological level.

Cumulative Effects of Culture

Our third point follows directly from our earlier point. There is reason to believe that cumulative experience of culture is stored and likely preserved in the brain (Kitayama & Salvador, 2017; Kitayama & Uskul, 2011). From the moment of birth (or even earlier), neural networks of the brain receive input from the external environment. The neural networks are gradually shaped, presumably through reinforcement-based learning (Morris, Fincher, & Savani, [Chapter 18](#), this volume), with a culture's beliefs and practices defining reward contingencies (i.e., whether and under what circumstances given behaviors are rewarded, not rewarded, or punished).

[Figure 3.1](#) (adapted from Kitayama & Salvador, 2017) illustrates this point. Kitayama and Salvador suggested that by its nature, a human brain engages with its external environment constantly. When the brain is recruited to produce a certain behavior to carry out any given task or to cope with certain adversities in a culturally prescribed fashion, it receives either positive or negative feedback from the culture. This feedback, in turn, positively or negatively reinforces, not just the behavior, but also all neural connections that are recruited to produce the behavior. This engagement and feedback cycle is repeated continuously for the duration of a person's entire life. Correspondingly, the changes made on the relevant neural networks accumulate in accordance with the rule of Hebbian learning, which states that neurons that fire together wire together (Gallistel & Matzel, 2013).

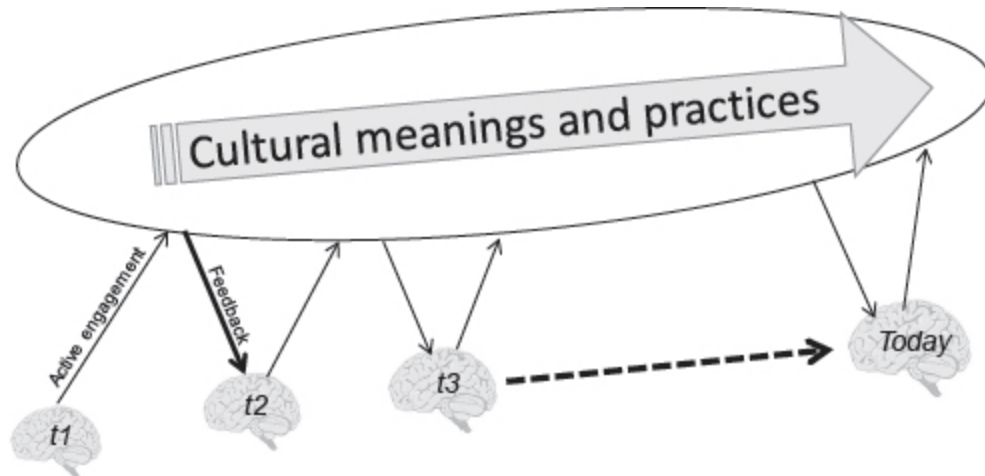

FIGURE 3.1. Shaping of the brain through reinforcement-based learning. Adapted from Kitayama and Salvador (2017).

This analysis makes one point rather clear. Cultural experience is likely to be stored and preserved in the brain. This may be the case even when the experience is long forgotten and unlikely to be recalled. It may not be suppressed or repressed in any Freudian fashion (although our framework would surely not preclude such possibilities). Every bit of cultural experience shapes certain parts of the brain and, when this shaping occurs, it remains in the brain by virtue of the neural connections that it strengthens or inhibits. Subsequent changes are added to the earlier shaping, but they may never fully replace it.

It is important to keep in mind that while cultural beliefs and practices may differ greatly within any given culture, there are some common elements that cut across this variability. They may correspond to core values and beliefs of different cultures, say, independence and interdependence or individualism and collectivism. Such core beliefs and values are therefore likely to leave certain characteristic cumulative changes in the brains that engage in the culture. Hence, “the neural networks . . . emerge through socialization encode and store cumulative cultural experience” (Kitayama & Salvador, 2017, p. 844).

This form of cultural influence that occurs over a long period through socialization is distinct from and, most likely, independent of effects of any immediate experiences of the “here and now,” including group pressures (Asch, 1956), various priming manipulations designed to activate certain

cultural constructs (Oyserman & Lee, 2008; Oyserman & Yan, [Chapter 20](#), this volume), images of others (Kitayama, Snibbe, Markus, & Suzuki, 2004) and goals (Chartrand & Bargh, 1996). These immediate factors of the “here and now” can be powerful. They build on the effects of long-term socialization and sometimes “bring out” the long-term effects of prior experience, while at other times they “mask” the latter. However, especially at a time of fast cultural change, the effects of immediate social situations may or may not correspond to the cultural information accumulated in the brain, and vice versa. As we see below, exploring the effects of long-term socialization or cumulative cultural experience may require researchers to take advantage of both newly invented tools (e.g., those for studying structural change of the brain) and novel conceptualizations of culture (e.g., those emphasizing repeated engagement in certain culturally prescribed tasks).

If the *cumulative* cultural effects are stored in the brain in the forms of, say, patterned neural connections and cortical, as well as subcortical, structural changes, then these effects may best be observed when the brain is directly probed through the use of neural measures. Indeed, there is every reason to expect neural indicators to be more reliable and faithful to culture’s influences on the mind. For example, as we shall see, brain indicators of a culturally acquired trait (e.g., holistic attention) are often linked reliably to a theoretical construct measured through self-report scales (e.g., interdependent self-construal). This, however, is not typically the case with performance-based measures of the trait (Kitayama, Park, Sevincer, Karasawa, & Uskul, 2009; Na et al., 2010). It may be the case that the identity of the self as independent or interdependent causes systematic biases in the nature of the cumulative cultural experience, which leaves very reliable traces in the brain. Any specific behaviors in the “here and now” are influenced by these traces, but they are also influenced, perhaps to a larger degree, by other, extraneous factors. Thus, these behaviors are distant, downstream, and rather noisy indicators of prior cultural experience.

Cultural Insight

Since culture leaves its traces in the brain, it has become possible to make new inferences about the nature of culture by examining the neural effects of culture. This “reverse inference” has become a new tool for investigating the nature of culture by going backward, contrary to the typical inference from culture to its effects on the brain. Thus, the neural traces of culture may enable us to discover fundamental features of culture that we might otherwise fail to note.

There is a growing body of evidence that in the processing of faces, Westerners (both Europeans and North Americans) tend to focus on the mouth region of the face, but Easterners (East Asians) tend to focus more on the eyes. Since an early behavioral demonstration (Yuki, Maddux, & Masuda, 2007), this hypothesis has received support from research using a more elaborate face recognition paradigm (Jack, Garrod, & Yu, 2012). Interestingly, this cultural bias in visual scanning (identified with a sophisticated eye movement analysis) can be reliably identified for 7-month-olds (Geangu et al., 2016). Moreover, consistent with this observation, earlier studies had documented that the so-called McGurk effect (wherein auditory perception of phonemes is biased by inconsistent lip movements), robust in Western populations, is substantially attenuated in Japanese and Chinese adults (Sekiyama, 1994, 1997; Sekiyama & Tohkura, 1991). As we see in a later section, in a series of studies that tested EEG signals, researchers have shown that the brains of East Asians tend to be “alerted” when exposed to human faces or face-like objects (presumably because the faces evoke a type of evaluation apprehension), whereas the brains of European Americans tend to be “relaxed” when exposed to such stimuli (presumably because the faces are linked to some sense of affirmation) (Hitokoto, Glazer, & Kitayama, 2016; Park & Kitayama, 2014).

Bringing these lines of evidence together, one may begin to see that when viewing another person’s face, people show remarkably different neuropsychological responses depending on their cultural backgrounds. Why is it that Westerners look at the person’s lips while feeling affirmed? Likewise, why is it that in the same situation, Asians look at the person’s eyes while feeling worried, concerned, or even threatened? Starting from these questions, one may begin to see, more clearly than before, that there are hidden dimensions in social interaction. Western social relations may be regulated by a principle of “mutual admiration or affirmation” (Kitayama &

Markus, 2000). Individuals may therefore focus on what another person is saying (resulting in a focus on the lips in face perception), which tends to be more positive and affirming, thus feeling safety in the experience. But East Asian social relations may be organized by a principle that may be called “mutual surveillance and criticism (Kitayama & Markus, 2000) through watchful eyes” (Kitayama et al., 2004). People may then focus on nonverbal indicators that may be hard to control (the eyes of the other person) to infer what the other person is “really” thinking, which may be relatively critical, resulting in the worry or threat response.

Admittedly, key data in an analysis like this do not have to be neural. Nevertheless, neural data may often prove to be crucial, because they are unlikely to be mediated by self-presentation or self-regulation. Instead, they are the culmination of long-term engagement in a culture’s reward contingencies. This feature of neural data enables scholars to make strong inferences on the nature of culture by examining the impact it has on the brain. It enables a “natural history” of socialization. Often archeologists learn a great deal about an evolutionary history by testing bones and other remains of animals, including humans, who once lived on the earth. Likewise, scholars of culture may learn much about the nature of their topic by testing its impacts on the human brain. This point deserves emphasis, because culture is typically tacit (Hall, 1982), with its most fundamental principles or dimensions hidden behind the surface, because these principles or dimensions are encoded not necessarily in each individual’s memory or conscious awareness but in culturally scripted social behaviors. Active participation and engagement in this cultural pattern leaves behind significant traces in the brain. Thus, these traces may provide a significant clue into the nature of such hidden principles or dimensions.

Theoretical Synthesis of Culture and Biology

The contributions of cultural neuroscience discussed so far concern different ways in which this approach enables the field to better understand the nature of both mind and culture. Cultural neuroscience, however, may allow us to go a step further, raising new questions about biology and evolution that undergird both the mind and culture. It may do so by highlighting the

fact that the brain and body represent an ultimate culmination of human biological evolution, while reflecting cultural influences. The neuroscience approach in cultural psychology may force researchers to rethink and reformulate the role of culture in human evolution, as well as the role of evolutionary processes in human culture (Sng, Neuberg, Varnum, & Kenrick, 2018).

It has been assumed that human cognitions, emotions, and other important functions of the mind have coevolved with sociocultural forms of living over the last 2 million years or so (Henrich, 2015; Mesoudi, [Chapter 5](#), this volume; Tomasello, 2014, 2016). However, it has yet to be fully appreciated that modern cultures that are intensively studied by cultural psychologists, such as cultures of honor, face, dignity (Leung & Cohen, 2011) and Eastern cultures or Western cultures (Markus & Kitayama, 1991), have evolved much more recently. These different cultures have likely differentiated gradually in Eastern versus Western regions of the Eurasian continent over the last 10,000 years, only after the emergence of sedentary forms of living that were grounded in different forms of subsistence such as farming, fishing, and herding (Talhelm et al., 2014; Talhelm & Oishi, [Chapter 4](#), this volume; Uskul, Kitayama, & Nisbett, 2008).

What might have transpired biologically during this relatively recent period (over the last 10,000 years) is not well known. But some speculations are possible. To begin, it is possible that divergent forms of culture that emerged during this period are based on biological evolution, because culture provided an important context for biological evolution (Chiao & Blizinsky, 2010; Kim & Sasaki, 2014). Moreover, the regulation of gene expression through epigenetic mechanisms is likely to be strongly influenced by cultural environments (Cole, 2014; Kitayama, Akutsu, Uchida, & Cole, 2016; Meaney, 2001). Needless to say, the brain is the result of natural selection; moreover, there is every reason to believe that the force of natural selection is in operation even after the establishment of culture. Hence, questions regarding the relationship between culture and evolution are now at the forefront of cultural psychological theorizing (Kashima, [Chapter 2](#), this volume).

As we see in later sections in which we discuss gene \times culture interactions, the emerging evidence is consistent with a general thesis that the human mind is based on a biological system that is prepared to

accommodate and respond to characteristics of the ecocultural environment and is therefore shaped, modified, and completed through the participation in this environment. Needless to say, the cultural environment itself is enabled and constantly reproduced with changes and modifications by the collective working of numerous minds that have been so shaped. At the dawn of modern cultural psychology, Shweder proposed that culture and the psyche make each other up (Stigler, Shweder, & Herdt, 1990). This thesis has since been elaborated by a number of subsequent researchers (Kitayama & Uskul, 2011; Markus & Hamedani, [Chapter 1](#), this volume; Markus & Kitayama, 2010). Cultural neuroscience has elaborated and expanded on the same thesis and illuminated how the brain and body may be transformed through culturally structured experience, as well as the genetic and epigenetic mechanisms underlying it.

CULTURE AND THE BRAIN

Having provided a general overview of the field of cultural neuroscience, we are now ready to discuss specific findings. In this section, we focus on how cultural variations in substantive domains (including self, cognition, emotion, and motivation) have been revealed in activation patterns of the brain. We further discuss potential cultural influences on more structural properties of the brain.

The Self

Much of the research in cultural psychology assumes that the form of the self varies across cultures (Markus & Kitayama, 1991; Triandis, 1989). In European and European American cultures, the self is said to be independent and individualistic. This form of self (called the “independent self”) is defined primarily by internal attributes such as traits, abilities, preferences, desires, and attitudes. Social relations are important, but they are seen as being derived from individual preferences and choices, as in romantic love. In contrast, in non-Western cultures, especially in Asian cultures, the self is said to be interdependent and collectivistic. This form of

self (called the “interdependent self”) is primarily defined by relational or social attributes such as social roles, obligations, or duties that come with such roles. Personal preferences do exist, yet they are seen as being relatively secondary and therefore are to be tamed and subordinated to social demands.

Abstract Traits as the Defining Feature of the Self

Early behavioral work used a Twenty Statement Test to show initial evidence for the distinction between independent and interdependent selves. In one early study, for example, Cousins (1989) had American and Japanese college students describe themselves in 20 different ways and found that the percentage of abstract personality descriptions (e.g., smart, honest) was higher for Americans than for Japanese. This pattern has been replicated in subsequent work with other Asian groups, such as Koreans (Rhee, Uleman, Lee, & Roman, 1995). This evidence is consistent with the proposition that the independent self is defined primarily by a set of internal attributes including abstract personality traits, whereas the interdependent self is defined more in terms of social or relational contexts. With this evidence alone, however, it is uncertain whether this cultural difference is due to linguistic conventions in describing the self or whether it is reflecting something deeper and fundamental about the nature of the self.

Ma and colleagues (2014) compared a Western sample (Danish young adults) with an Asian one (Chinese young adults) in an fMRI experiment. They used an experimental paradigm called the self-referential judgment task, in which participants are shown one personality trait at a time and asked to report whether the trait is descriptive of either themselves (the self condition) or someone who is famous (the public figure condition). A consistent and robust finding using this paradigm from previous studies using Western samples is that the medial prefrontal cortex (mPFC), particularly its ventral region, is engaged to a greater extent in the self condition than in the public figure condition (Heatherton et al., 2006; Kelley et al., 2002; Northoff & Bermpohl, 2004). The mPFC is interpreted to play a pivotal role in forming an evaluative judgment about the self, underscoring the hypothesis that self-perception is inherently evaluative. Moreover, given

the fact that personality traits and other abstract features of the self are used as stimuli, the finding might also mean that these abstract internal traits constitute the way the self is habitually represented in the brain.

When the procedure was repeated in the Danish sample in the Ma et al. (2014) study, the pattern was duplicated in a highly robust fashion. Importantly, however, when the Chinese sample was tested, the pattern was discernible, but much weaker compared with what was observed for Danes (Figure 3.2A). This finding is consistent with the hypothesis that the self is less likely to be represented in terms of decontextualized abstract traits among interdependent people. Supporting this view, the cultural difference in the mPFC activation in the self (vs. public figure) condition was explained by the fact that Chinese were more interdependent than Danes, as assessed by a well-validated interdependent self-construal scale (Figure 3.2B).

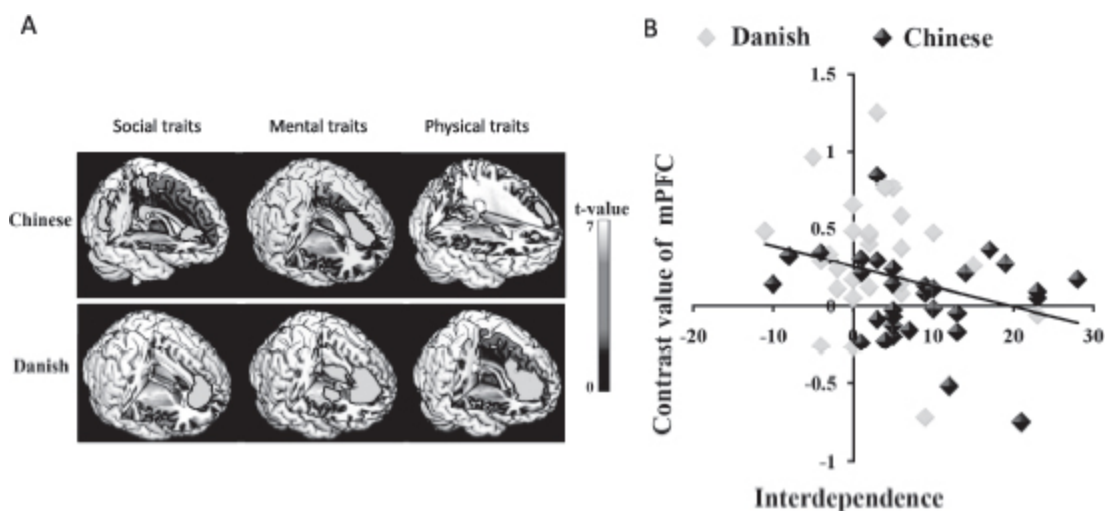

FIGURE 3.2. Activation of the MPFC in the self judgment condition relative to the public figure judgment condition in Chinese and Danish participants. (A) Areas activated in the self (vs. public figure) condition in reference to social, mental, and physical traits among Chinese and Danish participants. (B) The MPFC activation in the self (vs. public figure) condition is inversely predicted by interdependent self-construal. Adapted from Ma et al. (2014).

Neural Representations of the Self and Close Others

As noted earlier, the mPFC is engaged during self-processing (Heatherton et al., 2006; Northoff & Bermpohl, 2004; Qin & Northoff, 2011). Moreover, as shown above, the same effect is observed for Asians although it is less

pronounced. Building on this literature, Han and colleagues have investigated whether the mPFC region would also be recruited by close others for those with an interdependent self (Han, Ma, & Wang, 2016; Zhu et al., 2007). Such an outcome may be expected if close others are included in the self-representation of these individuals. In contrast, for those with an independent self, the self should be distinct even from close others. Hence, the mPFC region that is recruited by the self would not be recruited by close others for people high in independence.

Zhu and colleagues (2007) tested both Chinese young adults and Western young adult sojourners residing in Beijing. As in the prior self-referential judgement task, participants were shown a series of trait adjectives one at a time. They judged whether each adjective would apply to the self, their mothers (close other), or a public figure (the prime minister or the president). Replicating previous work, as compared to the public figure condition, the mPFC region was activated more in the self-judgment condition for Westerners. This effect was also observed for Chinese participants. Unlike results in the Ma et al. (2014) study reviewed earlier (Figure 3.2A and B), however, the effect was no stronger for Westerners than for Chinese participants. More work is needed to see whether there might be any selection bias that diluted the self-reference effect for Westerners who resided in Beijing. It is important to note, however, that the pattern of activation for the mother condition varied across cultures. For Westerners, it was no different than the pattern observed for the public figure condition, but for the Chinese it was no different than the pattern found for the self condition.

How robust was the shared representation of both the self and a close other for Chinese participants? As it turned out, the mPFC activation for various close others such as a father and best friend was lower compared to that for mothers even among Chinese participants (G. Wang et al., 2012), although the effect is comparable in strength for one's spouse and children (Han et al., 2016). The effect outside of China appears less consistent, with a failure to obtain the equivalent mPFC activation for the self and the mother among Chinese sojourners in the United States (P. Chen, Wagner, Kelley, Powers, & Heatherton, 2013), as well as a *larger* mPFC activation observed for the mother than for the self among Asian Americans (Huff, Yoon, Lee, Mandadi, & Gutchess, 2013). Thus, more investigation is warranted before

reaching a firm conclusion on cultural variation outside of China. One study suggested that the overlapping mPFC representation for the self and close others might be linked to the length of the close relationship and shared experience (Han et al., 2016). Last, but not least, in this work so far, the strength of mPFC activation during self- versus other-referential judgment is used as a face valid index of the interdependent self that “includes” close others in itself. No attempt has so far been made to explore similarities and differences in the neural representations within a given region, say, in the mPFC. Future work may benefit from adopting more refined indices such as resemblance of the voxel-level patterns of activation between the two conditions (Kriegeskorte, Mur, & Bandettini, 2008).

Self-Enhancement and Self-Criticism

Defining features of independent selves are not only abstract but also are likely positive rather than negative. There is a vast body of evidence showing positivity biases among American and European selves, often called self-enhancement, positive illusion, or the better-than-average effect (Dunning, Johnson, Ehrlinger, & Kruger, 2003; Taylor & Brown, 1988). In contrast, defining features of interdependent selves are more contextually represented and therefore need not be positive, especially in the context of mutually supportive relations. In fact, it has been argued that focusing on negative aspects of the self might be instrumental in fitting into such relations. Consistent with this argument, studies conducted with Asian participants tend to find these positivity biases less often (Heine et al., 1999). Moreover, in some cases, the self-enhancing biases are reversed to show self-critical biases among East Asians (Chang & Asakawa, 2003; Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997). Although important, this behavioral work left behind one significant question.

In particular, even though self-criticism has been found in studies that are carefully constructed to make sure that responses are anonymous (e.g., Kitayama et al., 1997), there still remains the question of whether East Asians intentionally presented themselves to be less desirable or more negative to conform to prevailing norms of modesty. With the self-report-

based studies alone, it is not easy to exclude this possibility, because self-report can be modified and edited if it needs to be.

To address this question, Hampton and Varnum (2018a) assessed whether European Americans and Chinese differ in positive versus negative self-views in an ERP study focused on the N400 component. The N400 is a negative deflection of electrocortical response in the midline regions approximately 400 ms poststimulus that is thought to index the detection of semantic or affective incongruity. In this study, participants were asked to judge the valence of positive and negative trait adjectives following a prompt indicating that the adjectives referred to the self or to others. European Americans showed stronger N400 responses when negative (vs. positive) traits words followed the self prompt, whereas Chinese participants did not. This is consistent with the idea that European Americans (but not Chinese) hold positive views of the self and therefore detect negative (vs. positive) traits as incongruent to the self. In addition, Chinese participants showed stronger N400 responses when negative (vs. positive) traits followed the prompt for an unfamiliar other, whereas European Americans did not, which suggests that Chinese may have an other-enhancing bias in addition to the lack of a self-enhancing bias (see also Sui, Hong, Hong Liu, Humphreys, & Han, 2013). This study also replicated previous self-report and behavioral evidence, providing further evidence for this cultural difference in self-enhancement.

Future research should extend the work reviewed here and explore potential boundary conditions. For example, all studies that show a self-critical bias among Asians use self-referential judgments, in which the self is foregrounded and explicitly focused on during judgment. It is possible that even among East Asians, the self is linked to positive feelings in subtle ways, which could come out when tested “implicitly,” without any overt reference to the self (Y. Chen et al., 2014; Kitayama & Karasawa, 1997). For example, alphabetical letters included in one’s own name are evaluated more favorably even among Asians (Kitayama & Karasawa, 1997). There may also be some conditions or contexts in which East Asians and European Americans hold comparably positive self-views. For example, East Asians may be particularly self-aggrandizing when their status is elevated or when their sense of face or honor (the public recognition of self-worth) is threatened. These possibilities should be addressed in future work.

Cognition

Previous cross-cultural studies have provided convincing evidence that thinking styles vary systematically across cultures (in this volume, see Masuda, Russell, Li, and Lee, [Chapter 8](#); Nisbett, [Chapter 7](#)). In particular, Nisbett, Peng, Choi, and Norenzayan (2001) amassed evidence indicating that whereas people in Western cultures tend to reason linearly, are more focused in attention, and have an analytic cognitive style, those in Eastern cultures tend to be more cyclical in reasoning, broader in attention, and overall, more holistic in cognitive style. It has been argued that analytic style is linked directly to independent self-construal, because more independent people tend to guide their actions, including their thinking, by their own goals. Thus, they see what they need or want to (focused attention), categorize what they see, and connect various objects in causal or quasi-causal terms through linear reasoning (i.e., *A* leading to *B*, which in turn leads to *C*). In contrast, interdependent people are more attuned to social expectations. Thus, they pay attention to social surroundings to figure out others' expectations and norms, which results in a broader scope of attention. They use various pieces of information regardless of self-goals or agendas, often accepting rather than resolving apparent inconsistencies to achieve a harmonious relationship with relevant others (dialectical reasoning) (see Grossmann & Kung, [Chapter 13](#), this volume; Varnum, Grossmann, Kitayama, & Nisbett, 2010). Existing evidence for the distinction between analytic and holistic cognitive styles is wide-ranging (see Masuda et al., [Chapter 8](#), this volume, for a more comprehensive review). Here we focus on three domains in which there is a fair amount of neuroscience evidence: holistic attention, spontaneous trait inference, and norm violation detection.

Holistic Attention

Early behavioral studies, such as the one by Masuda and Nisbett (2001), demonstrated a cultural difference in attention when participants were asked to perform a recall and recognition task of an underwater scene. Both European Americans and Japanese remembered focal fish equally well, but

Asians recalled more about the background scene than did European Americans. Moreover, Japanese (but not Americans) were able to recognize objects better in their original scene rather than in a novel one. A later study by Kitayama, Duffy, Kawamura, and Larsen (2003) showed a similar cultural difference in attention by having participants complete a series of line drawing tasks. Participants were shown a line embedded in a square frame, followed by a blank square of different size. In the relative task, participants were asked to draw a line identical in proportion to the original framed line, whereas in the absolute task, they had to draw a line identical to the original line, while ignoring the surrounding frame. The researchers found that European Americans were more accurate in the absolute task that required greater attention to the focal object, whereas Japanese were more accurate in the relative task, which required greater attention to context. The pattern that East Asians are more holistic than European Americans has been replicated across numerous other behavioral paradigms (see Miyamoto et al., 2013, for review). Moreover, this greater attention to relative positioning also shows up in the social realm, with Asians (vs. European Americans) showing a stronger brain response to social comparison information (Kang, Lee, Choi, & Kim, 2013).

However, the available evidence leaves some important theoretical questions unanswered. For example, it is not clear at what stages of processing the cultural difference might be observed. As in the case of self-enhancement, it is possible that the cultural difference may occur during an early stage of attention, but this issue needs to be investigated. Furthermore, it is not clear whether the broader scope of attention exhibited by East Asians is an obligatory process—a process that is spontaneously and automatically engaged. Nor is it clear whether the cultural bias in attention might be overridden with some cognitive effort. These questions have been subsequently addressed with neuroscience methods.

Kitayama and Murata (2013) presented to participants a series of images. A majority of them were standard stimuli (animal images), while the remaining images were infrequent, target stimuli (coffee mug) interspersed in the series of the standard images. Participants were to press a button when they saw target stimuli. The researchers found a reliable cultural difference around 200 ms posttarget, characterized as the N2 component, a reliable index of early orienting attention. The N2 amplitude was

significantly larger for European Americans compared to Asian Americans for the target. In addition, there was a greater slow wave component (an indication of cognitive elaboration) among European Americans in comparison to East Asians. These data support the hypothesis that European Americans allocate more attention to the goal-relevant focal object (coffee mug) early on in stimulus processing.

How about context processing? European Americans are likely to be less attentive to context, whereas East Asians are likely to be more holistic, allocating more attention to it. Goto and colleagues (2010) addressed this question with an ERP marker of expectancy violation (N400). In one experiment, European Americans and Asian Americans were presented with a target object (e.g., a crab) and asked to judge whether the object was animate or inanimate. Right before the object was presented, a contextual scene was presented briefly for 300 ms. Importantly, the scene was either thematically congruent or incongruent with the object (e.g., in the case of the crab, a beach vs. a parking lot). The N400 amplitude was significantly larger on incongruous trials than on congruous trials for Asian Americans but not for European Americans. This suggests that the context was actively processed by Asian Americans but not by European Americans. Moreover, the magnitude of the N400 incongruity effect was correlated with interdependent self-construal, which partially accounted for the cultural difference in the N400 incongruity effect.

In a relatively recent study, Russell et al. (2015) used a different paradigm and found a similar cultural difference in an N400 incongruity effect, with East Asians more likely to respond to contextual incongruity than European Canadians. In this study, European Canadians who were high in independent self-construal seemed particularly oblivious to contextual incongruity. Moreover, the same researchers have shown that Japanese subjects are especially sensitive to incongruous context when trying to retrieve the memory of the focal object (Masuda, Russell, Chen, Hioki, & Caplan, 2014). In this case, this sensitivity to the (potentially misleading) contextual information predicts compromised memory performance.

The priority East Asians place on context processing appears automatic and obligatory and, conversely, as does the priority European Americans place on object processing. However, this cultural difference may be

compensated for if extra processing resources are utilized. In an fMRI study, Hedden, Ketay, Aron, Rose Markus, and Gabrieli (2008) showed that such compensatory processes may in fact be recruited to negate the cultural difference in automatic, obligatory cognitive biases. In this work, the researchers used a modified version of the frame line task (Kitayama et al., 2003) in which the performance was allowed to be sufficiently high, so that there was no cultural difference in the performance of either the relative or the absolute task. This enabled the researchers to examine brain responses that were not confounded by performance. Under these conditions, when participants performed a culturally nonpreferred task (i.e., the relative task for European Americans and the absolute task for East Asians), there was a significantly greater activation in the frontoparietal attention network, which is thought to be responsible for a deliberate, top-down form of selective attention or effortful processing. This finding has been replicated with an alternative imaging method (functional near-infrared spectroscopy [fNIRS]; Murata, Park, Kovelman, Hu, & Kitayama, 2015). Moreover, using a different fMRI paradigm, Goh et al. (2013) replicated the greater effort allocation during the relative task among European Americans compared to Asians.

One interesting offshoot of the cultural neuroscience work on holistic perception focuses on face perception, which is generally considered to be Gestalt-like and therefore predominantly configurational or holistic; that is, the entire Gestalt may have precedence over specific features that make up the Gestalt. However, any given face may also be seen as a composition of various elements such as eyes, a nose, a mouth, and some other features. Thus, people may sometimes use these component features to recognize faces as well. Accordingly, one may assume that configurational (or holistic) processing is engaged for faces by default, regardless of culture. In contrast, compositional (or analytic) processing may be optionally engaged. The latter may be likely for those who are culturally trained to be analytic (Westerners), but not for those who are culturally trained to be holistic (East Asians). Miyamoto, Yoshikawa, and Kitayama (2011) manipulated similarities across different faces in terms of either general gestalt (by using morphing) or specific features (by varying the number of shared parts such as eyes and mouths). Perceived similarity of faces was influenced more by

Gestalt-like processing for Japanese, but more by feature overlap for Westerners (Miyamoto et al., 2011).

Recent neuroimaging research has extended the Miyamoto et al. (2011) finding, focusing on brain regions linked to face processing, in particular an area in the occipital/parietal lobe called the fusiform face area. This area exists in both hemispheres. The right hemisphere is generally linked to holistic, configurational processing, whereas the left hemisphere is linked to more compositional, feature-based or analytic processing. Since face processing is predominantly holistic, it is plausible that the right fusiform face area (the putative holistic processing area) may well be engaged across all cultures. However, the left fusiform face area (the putative analytic processing area) may or may not be engaged, depending on culture. One fMRI study exposed participants to a face (vs. a house control) and found that the fusiform face area is bilaterally engaged for European Americans, but the engagement is right-lateralized for Singaporeans (Goh et al., 2010).

Spontaneous Trait Inference

The fundamental attribution error was once one of the most replicable effects in social psychology. It was first described as the error most people commit when they try to make a causal link between dispositions and behavior, without accounting for situational constraints (Gilbert & Malone, 1995; Jones, 1979; Ross, 1977). Earlier on, this effect was believed to be inherent in the nature of human information processing (Nisbett & Ross, 1980). It was reasoned that because a person is a figure (rather than ground) in social perception, it naturally stands out in the perceptual field (Heider, 1958). It may then be anticipated that the person receives privileged processing in lieu of the context that surrounds him or her. This should presumably result in additional weight assigned to the person (relative to his or her context) when the social perceiver tries to account for his or her behavior.

However, subsequent cultural studies provided clear evidence that the initial, universalistic hypothesis is overstated (Morris & Peng, 1994; Miller, 1984). These studies began to show that the fundamental attribution error or the dispositional bias in social perception reflects culturally specific models

of the person. In cultures that sanction and reinforce a view of the person as independent and autonomous, the social perceiver looks for reasons for another person's behavior in internal traits, resulting in the dispositional attribution bias. However, in cultures that endorse a view of the person as an entity that is fully interdependent with the context (which includes other people, social norms, and expectations), the social perceiver looks for reasons for another person's behavior in the relationship between the actor and the context, thereby greatly attenuating the dispositional attribution bias. In support of this hypothesis, an fMRI study shows that East Asians are more likely to engage in spatial processing (indicating the processing of contextual information) than are European Americans, illustrating that certain spatial configurations of the context are being processed in conjunction with the focal behavior (Han, Mao, Qin, Friederici, & Ge, 2011).

One particularly powerful form of dispositional attribution, or the fundamental attribution error, is manifested as spontaneous trait inference (STI), which occurs when the perceiver automatically infers a disposition of another person upon observing a behavior of this person. More specifically, the perceiver encodes the behavior of another person by inferring a personality trait that corresponds to it, then assigns the trait to the representation of the person. Early on, the STI effect was shown to be quite robust among Americans (e.g., Winter & Uleman, 1984). Given the previous cultural hypothesis, it may be the case that Americans may routinely infer personality traits or dispositions from another person's behaviors and, as a consequence, this inference may eventually be automatic or spontaneous, carried out even when there is no need to do so. Moreover, from our cultural hypothesis it would also follow that Asians might not show any robust STI effect, since they do not routinely engage in dispositional inferences.

To address this issue, Na and Kitayama (2011) had participants memorize many pairings of faces and behaviors (e.g., checking a fire alarm before going to bed) implying a certain trait (e.g., careful). STI would occur if the participants automatically inferred the trait and attached it to the face. To find out whether this effect occurred, in the next phase of the study, participants were asked to perform a lexical judgment task while their EEGs were monitored. Right before the stimulus was shown, participants were exposed to a brief flash of one of the faces used in the memorization phase

of the study. Although participants were told to ignore this, as we saw earlier, face processing is highly spontaneous and automatic. Then, after they saw the face, it was followed by a word or nonword as the critical stimulus. When the critical stimulus was a word, it was either a trait that was matched to the behavior that had been paired with the face flashed on the trial (e.g., *careful*) or the antonym of the trait (e.g., *careless*). The researchers found that European Americans displayed an N400 in response to the antonym (e.g., *careless*), but not to the matched trait (e.g., *careful*). This demonstrates that when shown behaviors to memorize, the participants automatically inferred a corresponding trait and attached it to the face of the person. When shown the face during the lexical decision task, they also automatically recalled the trait linked to the face even if it was not part of the task. In contrast, East Asians showed no N400 regardless of whether the word was a matched trait or its antonym. Importantly, the greater N400 activity (in response to the antonym vs. the matched trait) was positively correlated with independent (vs. interdependent) self-construal (as assessed with the Singelis Self-Construal Scale), and this accounted for the cultural difference in the N400 antonym effect, indicated by a significant partial mediation.

Subsequent work extended the Na and Kitayama (2011) evidence in two directions. First, Varnum, Na, Murata, and Kitayama (2012) used the same N400 paradigm to assess STI and demonstrated an important within-cultural variation by social class. Specifically, European Americans of higher socioeconomic status exhibited a greater N400 antonym effect than those of low socioeconomic status, consistent with previous evidence that those of lower socioeconomic status pay greater attention to context and are therefore less prone to dispositional biases in attribution (Grossman & Varnum, 2011). Another study used the same N400 marker of STI and demonstrated another subgroup difference. Specifically, consistent with earlier work by Zárate, Uleman, & Voils, 2001), the N400 antonym effect tended to be weak among Hispanic Americans. Importantly, however, this effect became visible among those who were more acculturated into mainstream American culture and relatively more independent (Salvador & Lewis, 2017).

Norm Violation Detection

One dimension of culture that is distinct from, yet often correlated with independence and interdependence is the degree to which social norms are enforced either stringently or loosely—the dimension called tightness versus looseness (Gelfand et al., 2011). Gelfand and colleagues used a self-report-based measure of tightness versus looseness and have shown that individualistic countries (where independent self-construal is endorsed) tend to be loose, whereas collectivistic countries (where interdependent self-construal is endorsed) tend to be tight, although there are some notable exceptions. For example, certain Latin American countries or ex-Soviet countries are loose despite the fact that they are collectivist. Likewise, some Western societies (e.g., Germany) are tight despite the fact that they are relatively individualistic. Moreover, the societal-level tightness and looseness is linked to historical levels of man-made or natural threats. For example, tight nations have historically faced more disasters such as floods, cyclones, droughts, and greater territorial threats. The historical prevalence of pathogens and prevalence of tuberculosis and infant mortality are also related to greater tightness. Gelfand and colleagues argue that under high degrees of threat, stronger norms (and greater interdependence among people) may have been helpful in dealing with the threats.

In a relatively recent study, Mu and colleagues (2015) hypothesized that a conflict-monitoring system that is typically tied to the anterior cingulate cortex may be appropriated to detect social norm violations. To test this, they used the N400 component involved in the detection of semantic or affective violations, which is source-localized in the dorsal anterior cingulate cortex and its vicinity. Mu and colleagues had both American and Chinese participants judge how appropriate various behaviors (i.e., dancing) were in various situations, so that the behaviors were normal (tango lesson), weakly norm-violating (subway platform), or strongly norm-violating (art museum). Across cultures, a greater N400 component was consistently observed over the central parietal regions in the norm-violating versus normal conditions. However, the N400 for norm-violating versus normal behaviors was also evident at the frontal and temporal regions for Chinese participants but not for Americans. Evidently, the central parietal N400 activation that was observed in both cultures spread to the frontal region only in Chinese participants.

The cultural difference in the norm-violation N400 effect is consistent with previous self-report-based evidence that cultural tightness is higher in China than in the United States. However, it is not clear whether perceived tightness of social norms is sufficient to account for the cultural difference. Salvador, Mu, Gelfand, and Kitayama (2017) hypothesized that perceived tightness or looseness of social norms influences the spontaneous neural reaction to norm violations when individuals are prepared to engage socially and relate to other individuals. When the motivation to relate to others is chronically high (as may be assumed to be the case for Chinese, who are known to be interdependent), the neural system may be “tightened” or “loosened” depending on the perceptions of tightness or looseness of the relevant social norms, thereby modulating the magnitude of the norm-violation N400 response. The neural system may be “tightened”; that is, it is set to respond even when a signal of norm violation is very weak; conversely, the system may be “loosened”; that is, it is set not to respond until the signal of norm violation becomes sufficiently strong. However, when the motivation or readiness to relate with others is comparatively less (as may be assumed to be the case for Americans, who are known to be independent), the perception of the social norms will be kept dormant. In this case, the neural system of norm violation detection may tend to be disengaged regardless of the perceived tightness or looseness of the social norms.

According to this hypothesis, Chinese in the Mu et al. (2015) study may have shown a stronger norm-violation N400 response than did American, not only because Chinese perceived their societal norms to be tighter than that of Americans, but also because, compared to Americans, they were relatively more interdependent and were therefore more chronically relationally oriented toward others. By manipulating the relational orientation by using a well-validated priming procedure, Salvador et al. (2017) have provided initial evidence for the hypothesized joint influence of perceived tightness and the relational orientation on the norm-violation N400 response.

Emotion

Existing evidence shows that there is a great deal of commonality in emotion across cultures. For example, several prototypical emotions (called “basic emotions”) such as joy, anger, sadness, fear, surprise, and disgust are commonly recognized through facial gestures (Elfenbein & Ambady, 2002) or patterns of vocal intonation (Laukka et al., 2016). Moreover, cognitive appraisals associated with each of these emotions appear to be fairly common across cultures (Scherer, Shorr, & Johnstone, 2001). However, very much like classical music that is defined by a theme and its variation, these commonalities—or the themes of emotion—come with variations that are unevenly distributed across cultures. This point has been made most clearly in the area of emotion recognition. Due to variations in the expression of any given emotion across cultures, there is a small but robust ingroup advantage in the recognition of emotion, such that emotions expressed by ingroup members are recognized more accurately than those expressed by outgroup members (Elfenbein & Ambady, 2002).

High- versus Low-Arousal Emotions

Another important cultural difference lies in the value placed on high-versus low-arousal emotions. Tsai (2007; Tsai & Clobert, [Chapter 11](#), this volume) has argued that in European American independent cultures, individuals are motivated to express themselves and to use their internal attributes to influence others. In these cultures, emotions are therefore to be expressed clearly and perhaps to be up-regulated. In contrast, people in East Asian interdependent cultures are motivated to fit in and adjust to group expectations. In these cultures, emotions are to be moderated to achieve social harmony. In East Asian societies in particular, low-arousal emotions tend to be valued over high-arousal emotions, because high-arousal emotions are seen as too individualistic and therefore a hindrance to social harmony. Part of this cross-cultural variation in the value placed on high-versus low-arousal emotions might be due to the fact that independent cultures tend to be residentially more mobile over generations and therefore more heterogeneous in terms of ethnic composition (Rychlowska et al., 2015). In contrast, interdependent cultures tend to be more sedentary over generations and therefore be more homogeneous in terms of ethnic

composition. Thus, clear emotion expression may be less of a pragmatic necessity in interdependent, homogeneous (vs. independent, heterogeneous) cultures.

Much of the current evidence for a stronger value placed on high- versus low-arousal emotions in independent versus interdependent cultures comes from self-report ratings of the desirability of experiencing high-arousal positive emotions such as excitement and joy as opposed to low-arousal positive emotions such as calmness and relaxation. Do these ratings show anything more than culturally desirable responding? In a recent cross-cultural fMRI study, Park and colleagues addressed this question (B. Park et al., 2016). In this study, participants were shown images of others expressing high- or low-arousal positive emotions. To test the notion that different levels of emotional arousal are preferred in different cultures, B. Park and colleagues tested the activation of the ventral striatum (vSTR, a brain region involved in the experience of reward) in response to faces expressing either high-arousal happiness (excitement) or low-arousal happiness (calmness). Among European Americans, vSTR was activated equally strongly regardless of the arousal level. Interestingly, however, for Chinese participants, vSTR showed a greater activation when the faces showed low-arousal happiness than high-arousal happiness. This study provided the first support for the hypothesis that culture modulates the neurobiologically encoded reward value of perceiving others' high- or low-arousal positive emotions.

Emotion Regulation

The culturally divergent values placed on high- versus low-arousal emotions may have far-reaching effects on the regulation of emotions. In cultures in which high-arousal emotions are valued because they are supposedly expressive of the personal, independent self, and because they are highly instrumental in explicit communication, people might be quite reluctant to down-regulate their emotional expression. In fact, doing so might be counterproductive, because it goes against the strong value placed on emotion expression. Previous self-report studies conducted in Western cultures have provided convincing evidence that suppression of emotional

expression (called “expressive suppression”) is maladaptive. People who reportedly suppress their emotional expressions often tend to be less healthy and less happy than those who reportedly do not do so as frequently (Gross & John, 2003; John & Gross, 2004).

Recent cultural neuroscience work has built on this literature and has shown that emotion suppression is a culturally desired task for East Asians (but not for European Americans). Mauss and Butler (2010) examined autonomic responses during anger provocation and found a pattern typically associated with the motivational state of challenge (Mendes, Reis, Seery, & Blascovich, 2003) for East Asians if they strongly endorsed the value of emotion control. The challenge response indicates that an attempt to control anger is relatively routine and norm-congruous for East Asians (Tsai, Knutson, & Fung, 2006). In contrast, European Americans showed a different pattern of autonomic response that is typically linked to the motivational state of threat if they endorsed the emotion control value. This threat response supports the contention that controlling emotions goes against the norm of self-expression, likely less routine, and more effortful for European Americans (Markus & Kitayama, 1991; Tsai et al., 2006).

Will East Asians effectively suppress emotions when asked to do so? Murata and colleagues (2013) addressed this question. Both European American and East Asian participants were exposed to a series of negative or neutral images. When asked to suppress their negative emotions, East Asians readily down-regulated emotional arousal (captured by an ERP signal called the late-positive potential [LPP]; Keil et al., 2002; Luck, 2014; Schupp et al., 2000; Weinberg & Hajcak, 2010). This effect, however, was not in evidence for European Americans. In a recent study using a similar paradigm, Varnum and Hampton (2017) investigated whether these two cultural groups might also differ in the ability to up-regulate LPP in response to positive affective stimuli. This study showed that European Americans were able to enhance LPP in response to both positive and negative stimuli, whereas East Asians were not able to do so in this context. Varnum and Hampton also observed some trend-level evidence of stronger down-regulation of LPP among East Asians (vs. European Americans) when instructed to suppress emotional reactions, replicating the pattern observed by Murata and colleagues (2013). Taken together, these findings are consistent with the notion that cultural differences in the value placed on

emotion regulation and affect intensity are reflected not only in the external expression of emotion but also in the relative ability to control one's internal experience of emotional arousal.

Somatic Basis of Subjective Experience

Typically, emotional expression is seen as a manifestation of subjective emotional experience. However, there is a long line of thought that acknowledges the reverse causation, in which sensations derived from somatic, visceral, and/or behavioral responses of the body are thought to play a critical role in the construction of subjective feelings. As famously noted by William James, we may not cry because we are sad; instead we may feel sad because we cry. The possible causal role of somatic responses in emotional experience was addressed by Levenson, Ekman, Heider, and Friesen (1992), who observed that facial feedback effect (wherein patterned activation of facial musculature results in subjective experience corresponding to the emotion of the patterned face) is evident among Americans but not among people in a Sumatra village that had minimal contact with Western culture. They interpreted the cultural difference as showing that more socially oriented, interdependent people rely more on social relational information in the construction of emotion; therefore, somatic feedback from the facial musculature by itself might have little, if any, role in the construction of the subjective experience of emotion.

Recent cross-cultural fMRI studies by Immordino-Yang (2014; Immordino-Yang, Yang, & Damasio, 2016) have extended the Levenson et al. (1992) evidence. In particular, they scanned both Chinese and American participants while exposing them to video clips designed to elicit strong feelings of either compassion or admiration. Participants reported their feelings of either compassion or admiration as they watched the clips. Researchers tested the association between participants' subjective report of either compassion or admiration and the activation of the dorsal region of the anterior insula, an area of the brain that is believed to encode somatic and visceral sensations. Positive associations would indicate that individuals utilized the somatic or visceral information in calibrating the strength of their subjective feelings. When the two cultural groups were compared, this

association was significantly positive for Americans but not for Chinese participants. Thus, it appears that Americans actively utilized their somatic and visceral information in constructing their subjective feelings (Immordino-Yang, 2014). However, the Chinese evidently reported their feelings without taking the somatic and visceral information into account; that is, for Chinese participants, subjective feelings appeared to be dissociated from somatic or visceral sensations. This evidence is consistent with a claim that the Chinese “somatize” depression, that is, that suffering as evidenced in somatic sensations is experienced without entailing corresponding feelings of sadness and despair (i.e., depression; Kleinman, 1977, see Chentsova-Dutton & Ryder, [Chapter 14](#), this volume).

Another analysis by Immordino-Yang et al. (2016) reveals that the association between the anterior insula and subjective feelings increases as a function of emotional expressivity (assessed by a standard scale measure). First, the researchers find that Americans are more expressive than Chinese. Indeed, a mediation analysis shows that cultural difference in the association between the anterior insula and subjective feelings was accounted for (or mediated by) the cultural difference in the emotional expressivity (Immordino-Yang et al., 2016). If individuals are emotionally expressive, they may refer to their internal sensations more closely (after all, they have to find something inside to express). This internal attention may increase the correspondence between subjective feelings and somatic sensations. However, if people are not expressive emotionally, they may refer to other sources of information, including relational contexts in which the experience takes place or cultural norms about what the feelings should be. This in turn may diminish any link between subjective feelings and somatic sensations. Future work should extend this work to other cultural groups, particularly to Latinos, who are considered as interdependent as East Asians, yet emotionally more expressive than European Americans (Kitayama & Salvador, 2017).

Motivation

Culture also affects motivation (Kim & Lawrie, [Chapter 10](#), this volume). In East Asian societies, people tend to view the self as including close others

and to place more importance on relationships than do Westerners (Markus & Kitayama, 1991; Varnum et al., 2010). In a similar vein, compared to Westerners, East Asians are less motivated by a desire to express autonomy and uniqueness, and more attuned to social norms (Kim & Markus, 1999). Compared to Westerners, East Asians appear to be more sensitive to the threat of social evaluation (Kitayama et al., 2004). Recent cultural neuroscience research has followed up on these leads offered by prior behavioral work in this area.

Self- versus Other-Orientations

As we noted earlier in our discussion of the self, European Americans (who are relatively more independent) are more attuned to positive (vs. negative) self-relevant information than are East Asians (who are relatively more interdependent). This pattern may stem from a more general motivational orientation that prioritizes the self over other people around the self. As compared to interdependent individuals, independent individuals may be more motivated to pursue and realize the personal goals and interests that are unique to the personal self. Compared to independent individuals, interdependent individuals may be more motivated to pursue and realize goals and interests of ingroup members.

Researchers have investigated this possibility with self-report measures, asking directly whether “My happiness depends on the happiness of others” for interdependence or “I always try to have my own opinions” for independence. While responses to these questions are in fact used to define part of what independent versus interdependent self-construals are, they can be edited and modified intentionally when the individuals wish to do so. Thus, it is hardly possible to rule out the possibility that the individuals are responding in a socially and culturally sanctioned fashion even when they do not necessarily believe what they express (Kitayama & Salvador, 2017). As we discussed in the section on the self, it is possible that this type of tactical response management could influence the outcome greatly when the responses are measured with self-report. It is therefore important to use neural indicators that are hard to deliberately control.

This is exactly what Kitayama and Park (2014) tried to accomplish. In their experiments, both European American and Asian American participants performed a simple flanker task in order to earn reward points for themselves or for their best friends. They were told these points would be exchanged for gifts for the self or friend at the end of the study. When asked to report how hard they worked on the task for the self or a friend, no cultural differences were observed. For example, European Americans said they worked just as hard for their friends as they did for themselves, and this was not significantly different from East Asians assessments. However, the researchers also measured a neural response to an error when it was committed during the cognitive task. This response, called error-related negativity (ERN), is known to increase when the task at hand is motivationally more important. Moreover, ERN is known to occur nearly simultaneously with the initiation of the erroneous response; so there is every reason to believe that it is automatic, plausibly preconscious when it is initiated, and hardly possible to control. Kitayama and Park found that ERN was significantly greater in the self condition than in the friend condition for European Americans, consistent with the hypothesis that independent people motivationally prioritize the self over others, including their best friend. However, Asian Americans did not show a difference between self and other. Moreover, the ERN difference between the self condition and the friend condition systematically decreased as a function of interdependent self-construal, which in fact was higher among Asian Americans than among European Americans. Thus, the cultural difference in the motivational priority to the self (observed in the ERN measure) was mediated in part by interdependent self-construal.

Further support for the notion that self-construal plays a key causal role in the modulation of personal motivation comes from a recent fMRI study (Varnum et al., 2014) in which Chinese participants played a gambling game; some trials were played for the self, and others were played for a friend. When primed with an independent self-construal, participants showed stronger activation in the vSTR (a region linked to the experience of reward or pleasure) in response to their own (vs. their friends') wins. However, when primed with an interdependent self-construal, they showed comparable activation in the vSTR in the two conditions. The priming manipulation had similar effects on responses to monetary *losses* for oneself

versus one's friend, as indexed by right insula activity (a region linked to empathy for pain). The independence prime led to stronger right insula responses to one's own (vs. a friend's) losses. In contrast, the interdependence prime led to comparable activation of the right insula in response in the two conditions.

Last, but not least, in a series of studies, Telzer and colleagues have shown that Hispanics also show an interdependent pattern of neural responses (Telzer, Fuligni, & Galvan, 2015). For example, in one study (Telzer, Masten, Berkman, Lieberman, & Fuligni, 2010), they observed that compared to European Americans, Hispanics showed greater activation in the reward processing regions of the brain (vSTR) when they gained money for their family while losing money for the self. This is despite both European Americans and Latinos self-reporting that they enjoyed giving to their family equally. They interpret this cultural difference to be due to a commitment to family that is particularly strong for Hispanics.

Motivational Effects of Social Eyes

Early behavioral research provided a somewhat puzzling cross-cultural difference in cognitive dissonance. In a free-choice dissonance paradigm, individuals typically change their preferences after a choice, such that the preference for the chosen item increases, while that for the rejected item decreases (Brehm, 1956). This classical dissonance effect, however, does not happen in a standard free-choice paradigm among East Asians (Heine & Lehman, 1997). Subsequent research has suggested, however, that the absence of any postdecision dissonance effect among East Asians could be due to the fact that in the standard free-choice paradigm, the choice is completely private and anonymous (Kitayama et al., 2004). For interdependent selves, social relations are very important and, in fact, constitutive of the self. This means, for example, that whereas they are concerned with what others might think of them, they might not care much about some of the choices they make when no one is watching them. According to this reasoning, East Asians ought to show postdecisional attitude change if they are led to believe that other people could witness their choice. This prediction received support in a series of studies that

manipulated “social eyes.” For example, in one study, participants were seated in front of a poster that was composed of several schematic faces that appeared to be watching the participants. This subtle social eyes priming manipulation was sufficient to change the results dramatically. As the researchers predicted, East Asians now began to show a sizable postchoice attitude change. Interestingly, for European Americans in the social eyes priming condition, postchoice attitude change was attenuated.

Kitayama and Tompson (2015) proposed a biosocial model of affective decision making and integrated the cultural effects in postchoice attitude change within a broader theoretical perspective. Specifically, they hypothesized that the magnitude of decision conflict during choice (i.e., cognitive dissonance) is likely to be modulated by various cues indicating safety and threat. A brain system that monitors various conflicts (plausibly localized in the anterior/posterior cingulate cortex) is alerted and therefore sensitized when there is an impinging threat. For example, when you are driving a car and witness police in the distance, your system may be alerted to become more responsive to any existing conflict. Conversely, the conflict-monitoring system may be relaxed when there is a cue signaling safety. For example, when you are driving a car leisurely down a country road on a sunny afternoon, your system may be “relaxed” and become less responsive to any potential response conflicts. Note that once a conflict is detected during a choice, the decision maker will look for positive incentives in one of the decision options so as to be able to make a decision.¹ Consistent with this model, prior evidence shows that the magnitude of activation of the subcortical reward processing area (vSTR) during the decision predicts subsequent decision justification (Kitayama, Chua, Tompson, & Han, 2010). Without any conflict detected, this search for positive incentives will not be initiated, hence resulting in no postdecisional attitude change.

One important implication of the biosocial model is that the magnitude of the cognitive dissonance effect should depend on the sensitivity of a brain mechanism used to detect cognitive conflicts. The system of conflict monitoring is biologically grounded and likely to be available in all humans (and plausibly in all animals). However, culture can play an important role in the operation of this system by providing differing patterns of conditioning of both threat and safety to various significant stimuli. In particular, in social domains, others may serve as a cue of either threat or

safety, depending on specific patterns of cultural conditioning. In all cultures, people in one's social network are expected to be supportive. But cultures may vary in what it is that is considered to be most supportive.

Specifically, in independent cultures, a strong premium is placed on internal attributes of the self that are desirable and positive, as well as unique. People in the network are therefore expected to affirm each other's internal attributes. This social network of mutual affirmation may be an important anchor of the self-enhancement effects that are pervasive in European American cultures, as previously reviewed. In the present context, however, one important implication is that an image of these others, or what George Mead called the generalized other, may begin to signal safety that relaxes the system of conflict detection. This could explain why the cognitive dissonance effect is attenuated when European Americans have made a decision in front of the watching schematic faces; that is, the mere exposure to schematic faces may relax the conflict detection system, which in turn reduces the magnitude of a cognitive conflict experienced during the decision, thereby leading to a reduction of the choice-justifying attitude change.²

By contrast, in interdependent cultures, a much greater emphasis is placed on social duties, responsibilities, and obligations. People in the social network may therefore be expected to be relatively critical, making sure that nobody will fail to live up to the high social standards of performing duties and obligations. This network of mutual surveillance and criticism may underpin the self-critical biases reviewed earlier. As a consequence of engaging in this social network, a conditioning arises, such that the image of others in the network functions as a threat cue that alerts the conflict detection system. This could explain why the cognitive dissonance effect is augmented when Asians have made a decision in front of the watching schematic faces; that is, the mere exposure to schematic faces may alert the conflict detection system, which in turn augments the magnitude of cognitive conflict experienced during the decision, thereby leading to an accentuation of the choice-justifying attitude change.³

Although the biosocial model is consistent with known cultural effects in postchoice attitude change, specific assumptions of the model require closer scrutiny. To test the neuropsychological mechanisms postulated in the biosocial model, it is important to draw on neural measures to test whether

mere exposure to a face is sufficient to tighten or loosen the sensitivity of the conflict-monitoring system, depending on the culture of the participants. Note that a cognitive conflict that drives the postdecisional attitude change involves a mismatch between two choice options. Hence, it is analogous to a cognitive error, which occurs when there is a mismatch between an actual response and the representation of a correct response. Thus, one way to address this problem is to use a neural marker of error detection, known as the ERN (discussed earlier), to examine the cultural difference in the effects of face priming. In a recent study, both Asian and European American participants performed a simple cognitive task (J. Park & Kitayama, 2014). On each trial, right before the stimulus for the cognitive task was presented, participants were exposed to a brief flash of either a face stimulus or a control stimulus (either a scrambled face or an image of a house). Results revealed that the brief exposure to the face is sufficient to modulate the ERP response to errors during the cognitive task. Specifically, the sensitivity to errors as assessed by the ERN amplitude on error trials was greater in the face-priming condition than in the control condition for East Asians, but it was significantly smaller in the face-priming condition than in the control condition for European Americans.

This pattern has since been extended to a gamble paradigm (Hitokoto et al., 2016). In this study, both Asian and European American participants played a gambling task (Figure 3.3A). In the task, they were presented with two cards. Upon a choice between them, they were given feedback of either a gain or loss of points. Right at the beginning of each gamble, a schematic face (or a control picture [a scrambled face]) was briefly flashed for 90 milliseconds. One ERP component that is similar to the ERN is feedback-related negativity (FRN), a negative-going deflection of ERP approximately 270 milliseconds postfeedback around the midcentral electrode (as shown in Figure 3.3B). It is likely to reflect either expectation violation (resulting from the negative outcome), depression of reward processing (due to the absence of any reward), or both (Gehring & Willoughby, 2004; Hauser et al., 2014). In gambles, the outcome is just as likely to be positive and, with a win, there is a sharp positive deflection that arises around the same time window, called “reward positivity,” or rewP (Proudfit, 2015). The rewP reflects a type of mismatch that is positively rewarding vis-à-vis an expected outcome, rather than a negative or punishing one, as in errors or cognitive

conflicts. This positive mismatch called the “positive reward prediction error” will increase when the conflict detection system is alerted and sensitized.

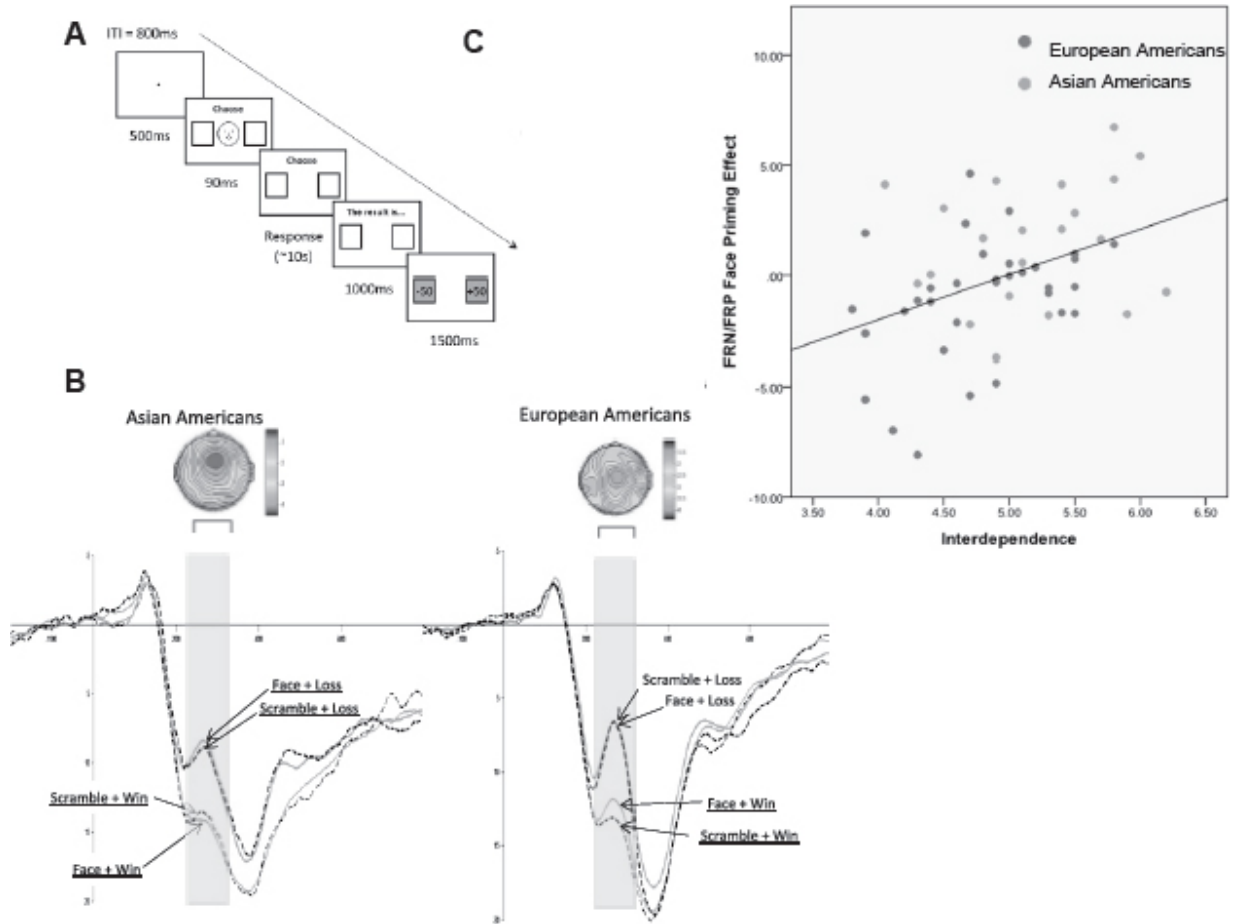

FIGURE 3.3. Face priming in a gambling task. (A) Trial structure. (B) Wave forms as a function of outcome and face priming for Asian Americans. (C) Face-priming effect as a function of interdependent self-construal. Adapted from Hitokoro, Glazer, and Kitayama (2016).

In short, to the extent that the exposure to a face increases alertness, both of these components (FRN and rewP) should increase in magnitude. This in fact was the case for Asian Americans (the right-side panel of [Figure 3.3B](#)). In contrast, if the exposure to a face causes the system to be “relaxed,” both FRN and rewP should decrease in magnitude. This latter effect was observed for European Americans (the left-side panel of [Figure 3.3B](#)). Importantly, when the combined magnitude of the two components was tested as a function of face priming, this face-priming effect was predicted

by interdependent self-construal (Figure 3.3C), as would be expected under the hypothesis that faces are more alerting for those with interdependent self-construals.

Brain Structure

So far, all the evidence reviewed concerns functional properties of the brain, namely, the degree to which brain mechanisms are activated under different conditions as assessed by the blood oxygenation level dependent (BOLD) signals in fMRI or by electrocortical responses measured on the scalp (ERPs). However, in recent years, an increasing number of studies have underscored significant impacts of experience on the brain volume of specific brain regions. This emergent body of evidence shows that experience can literally shape the brain, likely increasing the volume of brain regions that are recruited to carry out specific tasks, such as those involved in a job (e.g., cab driving; Maguire & Gadian, 2000), playing musical instruments, or other acts requiring visual-motor coordination (Draganski et al., 2004). Insofar as cultural experience entails intensive training in various tasks (Kitayama et al., 2009), long-term engagement in different cultures may result in variations in regionally specific brain volumes. At this point, this expectation has yet to be tested systematically. However, a few studies suggest that it deserves a concerted research effort.

Earlier on, Chee, Zheng, Goh, Park, and Sutton (2011) compared a large number of Singaporean Chinese and a matched sample of Americans to see whether any brain regions might differ between the two groups. Researchers assessed gray matter volume after controlling for total brain volume. They also investigated the thickness of cortical structures. As it turned out, several regions show greater volume, and increased thickness, for Americans than for Singaporeans. While the observed regions were diverse, they tended to be concentrated in prefrontal regions including the medial prefrontal cortex (mPFC) and the orbitofrontal cortex (OFC). Two more recent studies complement the Chee et al. observation by showing that the cortical volume of certain regions is reliably predicted by self-construal. First, Wang and colleagues (2017) tested Chinese young adults and found that the gray-matter volume of mPFC (the region that is typically activated in self-

referential processing) decreases as a function of interdependent (vs. independent) self-construal, with much of this effect due to interdependent (rather than independent) self-construal. Second, Kitayama and colleagues (2017b) tested young Japanese and found that the gray-matter volume of bilateral OFC systematically decreases as a function of interdependent self-construal, as illustrated in [Figure 3.4](#).

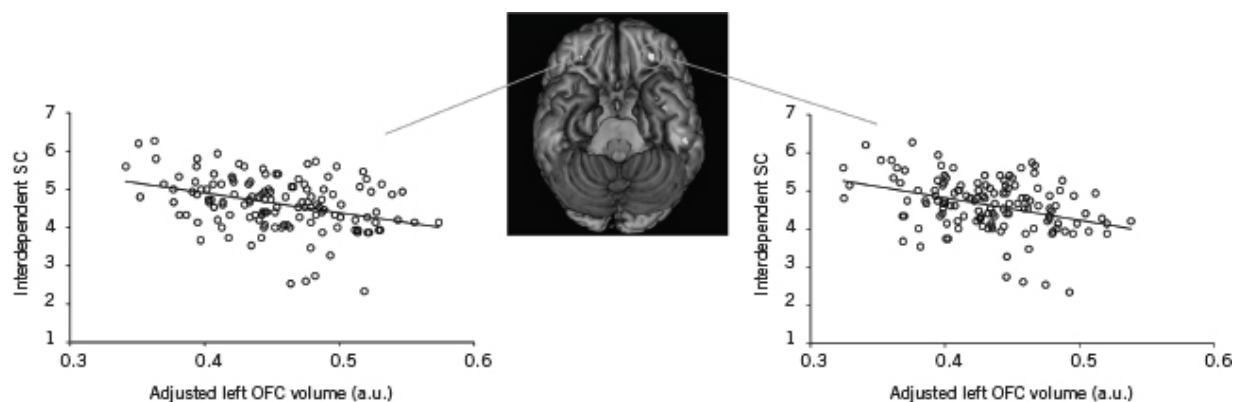

FIGURE 3.4. The association between the volume of bilateral orbitofrontal cortex (OFC) and interdependent self-construal. Voxel-based morphometry was employed to estimate cortical volume. The OFC regions were identified in a whole-brain analysis with a stringent statistical criterion (familywise error correction at the voxel level), which explains the small size of the regions of interest. Adapted from Kitayama, Yanagisawa, Ito, Ueda, and Abe (2017).

The three studies reviewed previously (Chee et al., 2011; F. Wang et al., 2017; Kitayama et al., 2017b) are loosely consistent. The regions identified as negatively correlated with interdependent self-construal (mPFC and bilateral OFC) are contiguous, both located in the prefrontal cortex (PFC). Moreover, to the extent that the gray-matter volume of these regions decreases as a function of interdependent self-construal, it should be greater for Americans (who are less interdependent) than for East Asians, which is exactly what Chee et al. (2011) observed. mPFC is believed to play a central role in self-referential processing, although this processing may also play a role in the processing of information about close others. Moreover, OFC is known to be critical in the monitoring of reward contingencies and decision making based on this monitoring (called “value-based decision making”) (Fellows, 2011; O’Doherty, 2011). The pattern observed so far in the cross-cultural evidence on brain volume is consistent with the hypothesis that East

Asians are less likely to engage self-related processes (as implicated in mPFC) or the monitoring of reward contingencies and the value-based decision making that accompanies it (as implicated in OFC) than are Westerners.

However, it is not clear why mPFC is identified in one study, while OFC is identified in the other. Moreover, Chee et al. (2011) failed to find any correlations between cortical volume and a measure of cultural values (which is different from the measure of self-construal used in the two more recent studies). Most importantly, all these studies are correlational and, as such, they do not justify any causal inferences. Thus, the cultural differences or the effects of interdependent self-construal on the cortical volume may be attributable to cultural experience, but they may at least partly be attributed to genetics. Future work must use training or interventions to clarify mechanisms underlying cultural variation in cortical volume. It may be sensible to focus on an age range (around puberty) in which cultural influences are likely to be maximal due to active neurogenesis (Giedd et al., 2006). This age range has also been identified as a “sensitive period” for cultural acquisition (Minoura, 1992). Alternatively, it may be useful to utilize genetic indicators of the susceptibility to environmental influences (as discussed in the next section on gene \times culture interactions) to test the extent to which plasticity in response to the environment may be involved in these cultural differences. If the cultural difference in brain structures is due to environmental influences, particularly to effects of cultural training, this difference may be expected to be more pronounced for those who show more effective cortical dopamine signaling for genetic reasons and who therefore presumably are more prepared to learn dominant cultural patterns (Kitayama, King, Hsu, Liberzon, & Yoon, 2016b).

CULTURE AND BIOLOGY

The bulk of evidence in cultural neuroscience pertains to brain processes for a good reason. After all, neuroscience refers primarily to the study of the brain. However, this exclusive focus on the brain might be too myopic and constraining; for the central nervous system is only one of two major biological systems that constitute the human. Another major system is the

somatic system, including the somatic nervous system. Moreover, both the central nervous system and the somatic system are inscribed in the genes; thus, their integrity relies fundamentally on the integrity of the genome and the systematic and coordinated expression of the genes in it. Thus, any review of the field would be remiss if it failed to explore both the biological body and genetics under the purview of cultural neuroscience. Fortunately, there has emerged a small but exciting literature pertaining to these issues in recent years.

Gene × Culture Interactions

Over the last few decades, researchers have observed that having a certain allelic variant of a particular gene does not determine any phenotype. To the contrary, the effect of the gene variant may depend on environmental conditions (Caspi, 2002; Caspi et al., 2003). These phenomena have been called gene × environment interactions. More recently, cultural researchers have pointed out that culture constitutes one aspect of human environments, putting forward a hypothesis that phenotypic effects of some select genes may depend on culture (Kim & Sasaki, 2014; Kitayama & Uskul, 2011). These hypothesized effects are called gene × culture interactions. A systematic exploration of these interactions may inform a theoretical analysis of how genes and culture may coevolve such that culture serves as a context for genetic selection and evolution, and as a consequence, various cultural traits are favored by resulting genetic factors. When genes and culture interact over evolutionary and historical time, their mutual influence is called gene and culture coevolution. We thus define gene × culture interactions as statistical interactions between allelic variants of a given gene and different cultural groups, wherein phenotypic expressions of a particular gene depend on culture. In contrast, gene–culture coevolution is an evolutionary or historical mechanism underlying the mutual influences between genes and culture.

Coevolution of Culture and Genes

Recent research in population genetics suggests that over the past 50,000 years of human history, numerous polymorphic genetic changes have been positively selected. Moreover, the rate of positive selection appears to have accelerated over the last 10,000 years (Ding et al., 2002; Hawks, Wang, Cochran, Harpending, & Moyzis, 2007; E. Wang et al., 2004). The exponential increase of genetic change is likely related to the massive increase in human population and exposure to new environments (including domesticated animals and plants). The increase in exposure to new groups and ecologies resulted in diversity of both infectious diseases and available nutrition (Rozin, Ruby, & Cohen, [Chapter 17](#), this volume). This is consistent with the hypothesis that genetic and cultural evolutions have proceeded in tandem (Eisenberg & Hayes, 2011; Feldman & Laland, 1996; Henrich, 2015; Laland & Brown, 2011; Mesoudi, [Chapter 5](#), this volume; Richerson & Boyd, 2004). Initial evidence for gene–culture coevolution analyzed how the effects of herding and milk production were related to the emergence of genetic mutations that support the digestion of lactose—milk sugar (Tishkoff et al., 2007). The mutations to digest lactose were rapidly incorporated in the population, which supported the growth of dairy culture. Another example comes from a close population-level link between specific polymorphisms of certain genes and tonal linguistic expressions that is independent of geography and history (Dediu & Ladd, 2007). It appears that these polymorphisms and tonal forms of linguistic communication coevolved. There are several other well-validated cases of gene–culture coevolution (see Mesoudi, [Chapter 5](#), this volume).

Far less certain is how the contemporary cultures including individualistic versus collectivistic cultures might have evolved in interaction with any particular genes (Chiao & Blizinsky, 2010) and, indeed, there has yet to be a convincing hypothesis in this regard (Eisenberg & Hayes, 2011). However, it remains a possibility that cultural variations in key psychological tendencies might reflect variations in the frequencies of certain key genotypes to some extent. Thus, more systematic research on this topic is warranted.

The Plasticity Allele Hypothesis

One alternative way of conceptualizing the interaction between culture and evolution is to focus on a possibility that evolution afforded a set of polymorphic variants or alleles of certain genes that predispose carriers of these alleles to more effectively learn cultural norms and rules. Cultural norms, values, and practices may be shaped by a variety of factors that operate over many generations, including ecology, subsistence systems, natural threats (or the absence thereof), immigration, settlements, and many others (see Kitayama & Uskul, 2011, for a review). According to this alternative way of thinking, genes may be implicated in determining the readiness to learn, accept, and internalize the culture's norms, values, and practices.

Belsky and Pluess (2009, 2013) argued that certain genetic alleles, most prominently, the varying number tandem repeat (VNTR) of exon III of the dopamine D4 receptor gene (*DRD4*) and the short (vs. long) allele of 5-*HTTLPR* of the serotonin transporter gene (*SLC6A4*) function as magnifiers of environmental influences. Carriers of these alleles are more likely to develop depression and other psychological disorders if exposed to early traumas and other adversities. However, carriers of these alleles are also more likely to develop *healthier* profiles (as compared to noncarriers) if brought up in advantageous environmental conditions. The plasticity allele hypothesis highlights an important variability in the data and thereby makes an important counterpoint to prior theories that portrayed these alleles as risk factors for mental illnesses. However, in and by itself, the hypothesis is agnostic about specific mechanisms by which the alleles might interact with environmental conditions to yield different mental health effects.

DRD4

Although several alleles have been referred to as plasticity alleles (Belsky & Pluess, 2013), one allele of the varying number tandem repeat (VNTR) of *DRD4* is particularly noteworthy in the context of cultural influence. Evidence suggests that some allelic variants of *DRD4* (called 7-repeat and 2-repeat variants) were incorporated into the human genome relatively recently over the last 50,000 years, during the period when humans spread “out of Africa” all over the globe. Moreover, these two relatively recent

variants of *DRD4* show a remarkable regional variation, such that the prevalence of these two variants increases as a function of distance from Africa (C. Chen, Burton, Greenberger, & Dmitrieva, 1999; Matthews & Butler, 2011). Tovo-Rodriguez and colleagues (2010) also found that among different South American groups, there were significant differences in allele distribution between recent and past hunter-gatherer and agriculturalist populations, with the 7-repeat allele of *DRD4* being more common among hunter-gatherers. *In vivo*, the 7- and 2-repeat variants are associated with increased efficiency in dopamine signaling. The neurotransmitter dopamine is most prevalent in prefrontal regions involved in executive functions, as well as in subcortical, striatal areas that are crucial in reward processing. Thus, it stands to reason that *DRD4* would modulate the efficiency of reinforcement-based learning of cultural rules, beliefs, and values (Kitayama et al., 2016b). As noted earlier (see [Figure 3.1](#)), this form of learning is likely to be central in the acquisition and subsequent internalization of cultural beliefs, values, and norms (see Morris, Fincher, & Savani, [Chapter 18](#), this volume). It may then be anticipated that carriers of the 7- or 2-repeat allele of *DRD4* are more likely to acquire and internalize norms that are salient in their environment.

Much of the evidence supporting this prediction comes from studies testing the effect of parenting quality on temperamental features of children. This work has so far been conducted with Western populations. The prevalence of the 2-repeat allele is quite low in these populations; thus, in all cases, researchers contrast children carrying the 7-repeat allele with those not carrying it. Evidence shows that overall higher-quality parenting is associated with better self-control and fewer externalizing problems. As predicted by the notion that 7-repeat carriers are more sensitive to reward contingencies that are conveyed by social environments, including parents, this relationship is more pronounced for the 7-repeat allele carriers (Belsky & Pluess, 2013; Sheese, Voelker, Rothbart, & Posner, 2007). Importantly, this effect has also been observed in intervention studies in which parents are trained for better parenting (Bakermans-Kranenburg & van IJzendoorn, 2011; Bakermans-Kranenburg, van IJzendoorn, Pijlman, Mesman, & Juffer, 2008; van IJzendoorn et al., 2011). The effects of parent training programs are particularly beneficial for children with the 7-repeat allele.

DRD4 and Culture

Kim and Sasaki (2014) have applied the plasticity allele hypothesis to explore various gene \times culture interactions. Their work focused on genes other than the VNTR of *DRD4*, particularly, the oxytocin receptor gene (*OXTR*) (Kim et al., 2011; Kim et al., 2010a; Kim & Lawrie, [Chapter 10](#), this volume) and the serotonin receptor gene (*5-HTR1A*) (Kim et al., 2010b) and reported initial evidence that they might also function similarly to *DRD4*. In one study, however, this group explored the effect of *DRD4* in the context of religious beliefs. Drawing on prior evidence that priming of religion increases prosocial behavior, Sasaki and colleagues (2013) found that this priming effect is more pronounced for carriers of the 7-repeat allele of *DRD4* as compared to noncarriers. The researchers interpreted the finding to suggest that the 7-repeat allele directly amplifies the priming effect. Alternatively, it may be that compared to noncarriers, carriers of this allele are more likely to acquire and internalize a cultural belief linking religion to prosocial behavior. Under this interpretation, it is because of the long-term effect of *DRD4* that the carriers showed a more pronounced priming effect than do noncarriers.

One prediction from the assumption that *DRD4* modulates the internalization of social norms is that carriers of the 7- or 2-repeat allele of *DRD4* should acquire values, beliefs, and norms of their culture to a greater extent than would their noncarrier counterparts. Kitayama and colleagues (2014) tested this possibility. A total of 398 young adults (both European Americans and East Asians living in the United States) were genotyped for *DRD4*. Approximately, 35% of them carried the 7- or 2-repeat allele, whereas the remainder did not. The participants filled out a series of questionnaires assessing constructs related to both independence (independent self-construal, self-esteem, self-efficacy, and value in self-expression) and interdependence (interdependent self-construal and holistic cognitive style), yielding higher-order factors of both independence and interdependence. The results are summarized in [Figure 3.5](#). As predicted by the hypothesis that the 7- or 2-repeat carriers tend to acquire the dominant norms and values of their culture, East Asians carrying these alleles were significantly more interdependent (or less independent) than their European American

counterparts. Interestingly, among the noncarriers, the cultural difference was negligible.

FIGURE 3.5. Independent versus interdependent social orientation as a function of both culture and *DRD4*. European Americans are relatively more independent, and Asians are relatively more interdependent; but this cultural difference is apparent only among those who carry high dopamine-signaling variants of *DRD4*. Adapted from Kitayama et al. (2014).

Consistent evidence has also been identified in the domain of emotional experience (Tompson et al., 2018). Specifically, in line with the hypothesis that emotional balance is culturally sanctioned among Asians and emotional positivity among European Americans, there was a significant culture \times *DRD4* interaction. East Asian 7- or 2-repeat allele carriers (versus noncarriers) reported experiencing greater emotional balance (i.e., weaker positivity bias) than noncarriers. For European Americans, however, the pattern was reversed such that the positivity bias was stronger, albeit nonsignificantly, among the carriers than among the noncarriers.

Additional evidence for the hypothesis that *DRD4* modulates the impact of situational influences comes from a recent study by Silveria and colleagues (2016), who tested the association between socioeconomic status and fat intake. Among girls living in low socioeconomic status

neighborhoods, fat intake tended to be higher if they carried the 7-repeat allele than if they did not; but among those in high socioeconomic status neighborhoods, fat intake tended to be lower for carriers than for noncarriers. There was no such effect among boys. The finding raises more questions than it solves. But one possible explanation is that social norms encourage foods with high fat content in low- (vs. high-) socioeconomic status neighborhoods. Moreover, these norms are likely to be more salient for girls than for boys. Thus, they might have had a greater impact on girls carrying the 7-repeat allele of *DRD4*.

Altogether, cumulative evidence suggests that *DRD4* does in fact significantly modulate the sensitivity or susceptibility to environmental influences, including parenting, religiosity, cultural values, emotion, and eating behavior. Moreover, the evidence is consistent with the hypothesis that this effect of *DRD4* is likely mediated by reinforcement-based learning of cultural norms, beliefs, and values (Kitayama et al., 2016b). Future work must examine this hypothesized mechanism in greater detail. In particular, neuroimaging methods may be employed to test the hypothesis that the 7- or 2-repeat allele of *DRD4* enhances reward processing. This process may in turn be conducive to enhanced capabilities for responding to reward contingencies in the environment, including those derived from sociocultural factors. Furthermore, it is of interest to explore how the reward contingencies in the environment might influence psychological processes. Would this influence occur at the level of explicit beliefs and values, as suggested by the Kitayama et al. (2014) study? Or, alternatively, would it also occur at the level of brain processes and mechanisms? Of course, the two possibilities are not mutually exclusive. At present, however, very few studies have tested the effect of *DRD4* on neural indicators of culture.

One thorny question to address is why *DRD4* and a relatively small number of select genes (Kim & Sasaki, 2014) have a singularly important influence on the acquisition of culture. It is possible that many other genes have similar functions, but they have not been identified so far. Another possibility is that these genes are in fact special in certain important ways. For example, these genes may serve as a “hub” in a network(s) of genes involved in cultural acquisition. Thus, the variations in them might have disproportionately large effects downstream, through the operation of other genes included in the network(s). For example, a gene network for reward

processing might have been previously established. This network might then be “turned on” and up-regulated through subsequent mutation of certain genes that influence this network. *DRD4* might qualify as one such gene. Although speculative, this possibility is consistent with a recent finding (noted earlier) that the key variants of this gene (the 7- and 2-repeat alleles) were incorporated into the human genome relatively recently (over the last 50,000 years).⁴

Culture and Biological Health

Another important extension of cultural neuroscience comes from recent efforts to examine correlates of biological health across different cultural contexts. There are two primary motivations behind this work. First, it is important to explore the extent to which culture goes under the skin, influencing not only the brain but also the body. Culture may influence the body in a way that has yet to be discovered through, say, certain forms of gene \times culture interactions or epigenetic pathways wherein cultural factors modulate expression of certain genes involved in pathogenesis. While these possibilities may seem no more than speculations at this point, all the evidence we have reviewed so far in this chapter points to their plausibility.

The use of biological measures in the investigation of cultural influences on health is important for another reason. In psychology, health has long been studied, but more often than not, measures of health are based on subjective self-reports. Most straightforwardly, researchers have used a single-item measure of subjective health, which itself has proven to be a valid indicator by reliably predicting mortality (Idler & Benyamini, 1997). Another typical example is a symptom checklist, in which respondents may be asked to check off all symptoms they feel or experience. A similar checklist is also used to assess chronic health problems and functional disabilities. These measures are often useful and valid. Indeed they are typically correlated with biological measures of health, for example, inflammatory markers such as interleukin-6 (IL-6) and C-reactive protein (CRP). Nevertheless, these subjective measures have an important limitation simply because they are subjective. A lot more is going on in the body that is not readily accessible to subjective reports. Furthermore, subjective

measures of health could produce artificially high correlations with a variety of sociocultural variables because they are aligned on an important valence dimension. Simply put, health is good, and as a consequence, to the extent that any sociocultural variables have shades of meaning that are positive (or negative), this shared valence component would ensure a degree of positive (or negative) correlation between health and these variables (Kitayama & Park, 2017). For example, as we shall see, when various negative emotions (e.g., general negative affect) are correlated with subjective health, the correlations are often highly negative. Moreover, these correlations occur regardless of culture. At first glance, the observation might show negative health effects of the negative emotions. Alternatively, however, these negative correlations might simply mean that there is a substantial common component (negative valence) shared in both the negative emotions and ill health. For this reason alone, it is important to explore correlates of health while assessing the latter with biomarkers.

Evidence available today on cultural variations in the correlates of biological health is rather limited. Much of it comes from matched, large-scale surveys conducted in both Japan and the United States (called the Survey of Midlife in Japan [MIDJA] and Midlife Development in the United States [MIDUS] surveys, respectively). The collection of biomarkers was completed relatively recently. Thus, only a few systematic comparisons have been conducted so far, and we hope that more comparisons are to come. Here we provide a glimpse into this effort to show that the cultural variation is in fact substantial.

Negative Affect and Biological Health across Cultures

In one earlier study, Miyamoto and colleagues examined a biological health correlate of negative affect by focusing on IL-6 (a commonly used indicator of inflammation, which in turn is a potent predictor of morbidity and mortality) (see Miyamoto, Yoo, & Wilken, [Chapter 12](#), this volume). It is typically assumed that negative affect is biologically taxing and should therefore be associated with poor biological health. In fact, as noted above, across cultures, negative affect is typically correlated inversely with subjective health to a substantial extent. To the extent that subjective health

and biological health are tapping the same reality (i.e., health), then this inverse relation between negative affect and health should hold across cultures. However, as also noted earlier, negative affect is obviously negative in valence; moreover, so is ill-health. Hence, part of the inverse correlation between negative affect and subjective health may be an artifact of this semantic overlap.

The possibility that the cross-cultural commonality of the positive association between negative affect and subjective ill-health might in part be a semantic artifact is reinforced by recent work on the cultural psychology of emotion, which suggests that European Americans seek positivity in the self, while avoiding negativity. For example, there is a strong motivational tendency among Westerners to pursue a positive self-image (Heine et al., 1999). Moreover, these two states (positive and negative) are experienced as incompatible, as suggested by inverse correlations typically found between positive and negative affect ratings in Western populations. Given this cultural emphasis on the positive, the experience of negative affect may be quite threatening to the self, since it can imply a certain inadequacy or even moral failure of the self (“I am not adequate or not living up to the standards of my culture”). In contrast, East Asians do not typically show any push toward the positivity that is common among European Americans (Heine et al., 1999). Instead, they tend to have a more dialectical view of positivity and negativity, wherein the two states are mutually compatible and require one another to complete the full experience of emotion (Miyamoto & Ryff, 2011). Consistent with this hypothesis, among East Asians, the correlations between positive and negative affect tend to be either null or even positive (Kitayama, Markus, & Kurokawa, 2000; Miyamoto & Ryff, 2011). Hence, among East Asians, the experience of negative affect is unlikely to be threatening to the self.

In support of this analysis, when Miyamoto et al. (2013) correlated negative affect that was experienced “in the last 60 days” with IL-6, the correlation (after controlling for common covariates such as body mass index [BMI], age, sex, and education) was significantly negative among Americans, but virtually zero among Japanese. Although this original investigation focused solely on one biomarker, the same hypothesis has recently been tested with three additional biomarkers, including one additional inflammation marker (CRP) and two markers of cardiovascular

risk (systolic blood pressure and the amount of low-density lipoprotein [LDL] cholesterol). The pattern has held up across the measures (see Kitayama et al., 2017a).

Anger Expression and Biological Health across Cultures

Another emotional state that is typically considered linked to compromised biological health is anger (Chida & Steptoe, 2009; Smith, Glazer, Ruiz, & Gallo, 2004; Thomas & Nelesen, 2004). However, earlier on, J. Park and colleagues (2013) provided evidence that anger is not a monolithic emotion. Instead, it may have two contrasting prototypes that are differentially salient across cultures. First, anger is often construed as a venting of frustration. When frustrated, people vent by expressing anger. This form of anger is likely to be more dominant or salient in individualistic societies in which people have clear personal goals and are therefore prone to frustration in difficult life circumstances. Second, however, anger may also be construed as a display of dominance and status. When given a dominant, higher-status role, individuals may feel the privilege of expressing anger so as to show off their status. This form of anger is likely to be more prevalent and salient in collectivistic societies in which people are ranked in a strict fashion and only those high in status are permitted to express the emotion of anger that is otherwise seen as socially disruptive (J. Park & Kitayama, in press; J. Park et al., 2013). In support of this analysis, J. Park and colleagues found that among Americans, social status is inversely correlated with anger expression, so that lower-status Americans are more likely to report that they express anger than are their higher-status counterparts. In contrast, among Japanese, social status is positively correlated with anger expression, so that higher-status Japanese are more likely to report that they express anger than are their lower-status counterparts.

Based on the J. Park et al. (2013) findings, it may be assumed that anger expression is typically associated with compromised health in Western societies, not so much because anger expression is inherently unhealthy but because those who express anger in these societies tend to have more frustrating experiences, which in turn may have compromising effects on biological health. One critical test of this is to analyze the relationship

between anger expression and biological health in societies in which anger is a privilege that is allowed only to higher status individuals. Kitayama and colleagues (2015) tested this prediction in a recent study and provided initial support for the prediction. As shown in Figure 3.6, whereas anger expression (assessed with a standard measure (Spielberger & Sydeman, 1994)) was associated with higher biological health risk as assessed by both inflammation (IL-6 and CRP) and cardiovascular malfunction (blood pressure and amount of LDL cholesterol) among Americans, it was associated, equally significantly, with lower biological health risk assessed in the same way among Japanese. The culture \times anger expression interaction was highly significant after controlling for age, gender, BMI, and chronic conditions, all of which were related systematically to biological health risk.

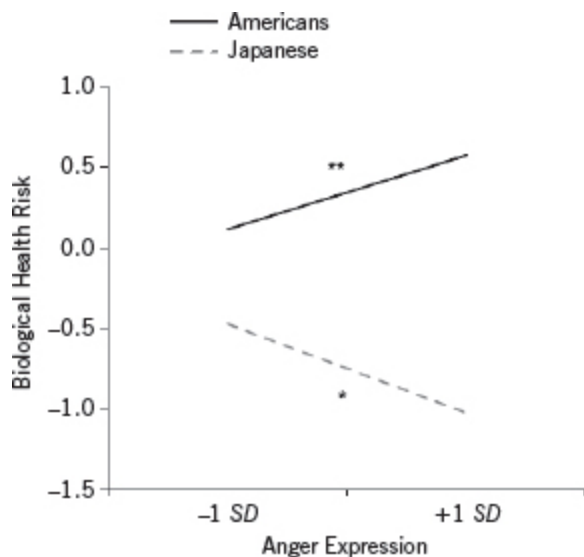

FIGURE 3.6. Biological health risk as a function of anger expression among Americans and Japanese. Biological health risk is indexed by a composite of four measures assessing inflammation (IL-6 and CRP) and cardiovascular malfunction (blood pressure and total to HDL cholesterol). Adapted from Kitayama et al. (2015).

Neuroticism and Biological Health

How about neuroticism, a personality disposition linked to various negative emotions such as anger, anxiety, and guilt (Costa & McCrae, 1987; Goldberg, 1992)? If neuroticism were linked to these negative emotions and,

moreover, if these negative emotions were linked to poor biological health, neuroticism would also be linked to poor biological health. However, we have already seen that negative emotions might not be necessarily linked to lowered biological health, especially among Japanese (Miyamoto et al., 2013). In fact, expression of one of these emotions, anger, is clearly linked to better biological health among Japanese (Kitayama et al., 2015; see [Figure 3.6](#)). Both negative affect and anger expression are positively correlated with neuroticism, although there is reason to believe that neuroticism is a stable individual difference that is distinct from affective states that vary as a function of circumstance. It would seem worthwhile, then, to examine the relationship between neuroticism and biological health risk across cultures.

This is exactly what Kitayama and colleagues (2017a) attempted. Using the same MIDUS/MIDJA dataset, the researchers predicted biological health risk as a function of neuroticism (assessed by the degree of endorsement of traits such as worried, upset, irritated, and calm [reversed]) after controlling for a standard set of covariates, and found another striking cross-cultural difference. Among Japanese, higher neuroticism predicted lower biological health risk; that is, neurotic Japanese were biologically healthier. Among Americans, however, there was no reliable relationship between neuroticism and biological health risk. Although the cross-cultural difference might seem surprising, Kitayama and colleagues had anticipated it. They argued that neuroticism is negative because it fosters attention to potential dangers and threats in the environment. This attention can be maladaptive if people have no means at their disposal to cope with such dangers and threats. However, Japanese are more likely than Americans to be flexible, willingly adjusting their behaviors to the dangers and threats so as to minimize any negative effects of these dangers and threats. They are therefore likely to be challenged (rather than threatened and helpless), resulting in reduced biological health risk. Kitayama and colleagues measured the propensity to flexibly adjust one's behaviors to environmental contingencies and provided evidence for this analysis.

CONCLUSIONS

Summary

Our main aim in this chapter has been to present an overview of a neuroscience approach to cultural psychology. We highlighted several possible benefits of this approach. First, the neuroscience approach focuses on brain structures and functions when theorizing about the mechanisms underlying various psychological phenomena and cultural variations in those phenomena (*psychological mechanisms*). Second, recent evidence regarding the extent of human neuroplasticity makes it apparent that environmental influences, including cultural influences, can go deep under the skin. This evidence challenges the more traditional computer metaphor of the mind, wherein culture is thought to regulate only the inputs and outputs of an autonomous psychological system, without influencing the system itself (*biological plasticity*). Third, cultural influences at the neural level can be more reliably linked to cumulative cultural input, since cumulative cultural experience is stored and preserved in neural networks (*cumulative effects of culture*). Fourth, neuroscience can help us uncover new psychological phenomena that vary across cultural groups, of which we may not have been aware if we used more traditional behavioral or self-report methods (*cultural insight*). Fifth, and perhaps most important, the neuroscience approach makes it possible to pursue and eventually realize a theoretical synthesis of culture and biology or nurture and nature (*theoretical synthesis of culture and biology*). By realizing this synthesis, a more comprehensive understanding of the human mind—as a biological system that is fully embedded in and attuned to beliefs, values, and practices inherent in the sociocultural environment—can be achieved.

We illustrated these points by reviewing (1) several substantive domains of research on the relationship between culture and the brain; (2) gene \times culture interactions, with a focus on *DRD4* in addition to gene–culture coevolution; and (3) cross-cultural variations in the correlates of biological health. Biological responses underlying known cultural variations in some significant psychological functions illuminate the specific mechanisms of these cultural effects, which in turn bring up new questions about how these effects have come about, leading to recent work on gene \times culture interactions. Moreover, the same biological approach to culture has begun to reveal the profound extent to which sociocultural processes are implicated in biological health.

Limitations

Having taken stock of what the field has accomplished so far, it is fitting to step back and consider some important limitations to the body of literature produced by this emerging discipline. Four limitations deserve discussion. First, as in the rest of cultural research, the bulk of evidence is limited to a comparison between Westerners and East Asians. Although some studies have begun to include other cultural groups in cross-cultural comparisons, such as Latinos (Hampton & Varnum, 2018b; Kitayama & Salvador, 2017; Telzer et al., 2010), much more remains to be done to capture human cultural diversity using neuroscience methods. As these methods are typically labor-intensive, expensive, and not highly portable, expanding the database to include broader samples (e.g., residents of remote and small-scale societies) is logistically challenging. All the more, such work should be carefully designed so as to yield the greatest insight into the consequences and causes of cultural variations.

Second, much more concerted effort is needed to integrate cultural and evolutionary frameworks. Whereas the brain and body are genetically programmed at one level, they are deeply influenced by sociocultural environments. Moreover, recent research on the time course of genetic evolution makes it apparent that genetic evolution is inseparable from the evolution of culture. This coevolutionary dynamic must be more thoroughly theorized and empirically investigated. In so doing, methods of neuroscience, genetics, and epigenetics would be indispensable insofar as genes, and the expression of the genes, are one major means by which culture and biology interact. Indeed, the coevolution of culture and genes may occur in terms of not only the selection of certain genetic polymorphic variants but also the modification of how existing genes are transcribed and expressed. Just as the selection of genetic alleles may be conditional to environmental contingencies whether ecological, climatic, or otherwise cultural, the epigenetic pathways that emerge might also be conditional to such contingencies that are relatively stable over generations. Recent developments in epigenetics (Cole, 2014; Meaney, 2001) may be instrumental in developing new insights on cultural evolution. This effort must be combined with emerging theories regarding the impact of evolutionary factors on cultural variation, cultural change, and cultural

evolution (Diamond, 1998; Henrich, 2015; Oishi, 2014; Sng et al., 2018; Talhelm & Oishi, [Chapter 4](#), this volume; Thompson et al., 2018; Varnum & Grossmann, 2017; Varnum & Kitayama, 2017).

Third, the hypothesis that genetics and epigenetics are deeply involved in cultural influences underscores the need to investigate sociocultural variations in brain structures in much finer detail. Pertinent evidence that is available today is limited in quantity, since there are only a few published studies. There is also limited evidence about the measures used, since typically only gray-matter volume (and, in one case, cortical thickness) was tested. However, there are many other structural properties. Particularly, future work may benefit from careful consideration of anatomical connectivity across different regions of the brain, as well as how they may interact with certain genes (including *DRD4*) that are demonstrably implicated in cultural evolution.

Fourth, most of the findings in cultural neuroscience are correlational. Such studies can help us identify ways in which cultural groups differ and may suggest mechanisms, but to truly understand why these differences exist, experiments are required. Future work would benefit from studies utilizing various manipulations and interventions that are theoretically motivated and targeted to specific mechanisms of interest (including not just psychological processes and situational factors but also specific biological systems).

Future Directions

Despite these limitations, the field of cultural neuroscience has matured over recent years and has contributed a great deal to the knowledge base of cultural psychology. We envision that over the next decade or so, some methods from this field may be incorporated into the mainstream of cultural psychology, particularly as costs come down. For example, the use of EEG and ERP in cultural psychology may become ubiquitous, much as reaction-time-based measures have become commonplace in cognitive psychology and social psychology over the past several decades. Expanding the cultural psychologist's toolkit will enable greater sophistication and theoretical precision by providing insight into process and mechanism. It

will help avoid common pitfalls that have troubled the field, such as cultural differences in response biases, social desirability, and issues inherent in translation. It will also likely uncover novel domains of cultural difference and may even change some fundamental ways in which we conceptualize certain phenomena. For these reasons alone, cultural neuroscience is indispensable for further development of theory and research in cultural psychology.

This brings us back to our initial question: Why neuroscience? Our review of the first 10 years of research in cultural neuroscience presents one response to this question. We trust that each reader will critically evaluate this response. As three of the proponents of the field, we believe that the case we have presented for the field is reasonably strong. While there are many specific instances in which critical evidence is still lacking or the theoretical analysis has yet to be made airtight and compelling, they do not necessarily represent a liability to the field. To the contrary, each of these “soft spots” in the current undertaking may be precisely the ones that define important points of departure for the next 10 years of the study of culture from a neuroscience point of view. With this caveat, we hope everyone agrees that the prospect of the field is promising. Indeed, the field may well be deserving of further investment by the next generations of talented researchers.

NOTES

1. It bears an emphasis that the traditional view of cognitive dissonance assumes that a conflict detected during choice activates negative arousal (dissonance), which is reduced through postdecisional rationalization. In contrast, the Kitayama and Tompson (2015) model hypothesizes that the in-choice conflict initiates a search for positive incentives that would enable the decision maker to make a clear choice. According to this model, what would appear to be postdecisional rationalization is in part realized before the choice is made, through the identification of decision-enabling positive incentives.

2. The interpretation presented here is different from that in an earlier analysis. For example, Imada and Kitayama (2010) argued that European Americans feel “social pressures” from the faces, which in turn diminished the need for rationalization. The two interpretations are not mutually exclusive and must be further investigated in future work.

3. An alternative interpretation is to assume that Asians are worried about what others might think of them when exposed to “social eyes” (Imada & Kitayama, 2010; Kitayama et al., 2004). This interpretation is consistent with the current analysis insofar as the anxiety associated with evaluation apprehension may also alert the conflict detection system.

4. This consideration might be part of the reason why the evolution of this gene appears to coincide with dramatic turns in the human way of being, particularly, the dispersion of humans into the Eurasian continent (50,000 years ago) and the beginning of herding, farming, sedentary living, and eventual formation of non-kin-based, large social groups (over the last 10,000 years). This speculation, however, must be tempered with a realization that there might be other genes or epigenetic processes that are functionally similar. Moreover, cultural evolution depends on a large number of factors that are fundamentally ecological, geographic, and historical (e.g., Diamond, 1998; Talhelm & Oishi, [Chapter 4](#), this volume; see Markus & Hamedani, [Chapter 1](#), this volume, on “downward constitution”). Hence, it would be not only simplistic but also incorrect to link civilization singularly with any particular genes.

CHAPTER 4

Culture and Ecology

Thomas Talhelm and Shigehiro Oishi

Ecological psychology has boomed from a rare form of psychology to a flourishing field, including psychologists, sociologists, and economists. We review the development of the field, from early studies to more recent advances in subsistence theories, environmental challenges, human environments, economic environments, and political environments. We also discuss frequent challenges in ecological psychology, such as reverse causality and ecological determinism, as well as ways to address these challenges. Finally, we outline paths forward including understudied regions and micro cultures.

During the cognitive revolution, psychologists mostly assumed that the human mind is like a computer. In that metaphor, computers process information the same way whether they are in Beijing or New York. But in the 1980s and 1990s, some psychologists became fascinated with the idea that even basic processes such as thought and perception could be different in different cultures. For the next few decades, cultural psychology boomed. Psychologists rushed to find differences in the way people think and relate to people.

But amid the rush to find differences, most of the researchers left one critical question for later: Where do these differences come from? Psychologists have made sporadic attempts to try to explain cultural differences in the past. But in the last 10 years, psychologists have started devoting more time to testing different theories of cultures' origins. This

chapter reviews research on one type of explanation: ecological theories of culture.

WHAT ARE ECOLOGICAL THEORIES?

Ecological theories see culture as a response to the demands of the environment. That environment may be literal, such as mountains and rainfall. The environment is clearly a strong explanation of why sailing is central to Pacific Islander culture and why farming was an important feature of American culture but not Inuit culture.

The environment may also be more figurative, more social (for reviews of social ecology, see Oishi, 2014; Oishi & Graham, 2010). For example, the number of times people in a community have moved within the last 10 years is a part of the environment, and it can influence how likely people are to know their neighbors (Pettit & McLanahan, 2003; for a review, see Oishi, 2010). The environment may even be something nonphysical and hard to measure, such as how much people in a nation trust strangers (Fukuyama, 1995). And sometimes the environment is both concrete and man-made, such as the unending uniformity of American suburbs (Oishi & Talhelm, 2012).

EARLY ECOLOGICAL STUDIES

Early Ecological Anthropology

In his review of anthropology, Helm (1962) argued that the founders of anthropology were ecological. There were the early anthropologists Edward B. Tylor (the author of the 1871 book *Primitive Culture*) and Lewis H. Morgan (the author of the 1877 book *Ancient Society*), who saw technological advance as a major ecological variable that drives cultural change. From the start, much anthropology was ecological.

Early anthropologists also studied the types of subsistence styles that the environment made possible. For example, the North American plains supported large herds of buffalo. Egypt's Nile River supported farming.

Anthropologists Friedrich Ratzel and Otis T. Mason wrote about the importance of these types of “food areas.” The influence of food environments is the most obvious in harsh environments, such as the arctic environment of Inuit culture.

As far back as the 1930s, when anthropologists described different cultures, they spent much time on the environment. For example, C. Daryll Forde described the environment of cultures around the world, from African Masai cattle herders to Hopi farmers in North America, in his 1934 book *Habitat, Economy and Society*. Alfred L. Kroeber (1947) divided North America into different subsistence and cultural regions. In his 1936 book, *The Economic and Social Basis of Primitive Bands*, Julian Steward argued that hunting and gathering is best suited to a patrilineal social structure.

Yet not all of anthropology was ecological. Hallowell (1949) explicitly criticized anthropologists for ignoring the environment. He argued that many anthropologists implicitly assume that “culture is a phenomenon *sui generis*,” or born out of thin air (p. 36). In his own research, Hallowell used ecological data to understand the hunting systems of Algonquian tribes in North America. He analyzed variables such as the size of hunting grounds, the size of hunting group, and the ratio of active hunters to others. He also analyzed the resources available in different environments, such as which environments had lots of fur animals and different food types.

Historical Materialism

Arguably the most influential ecological theory was Marx’s historical materialism (Marx & Engels, 1970). Marx’s theory held that production systems are essential to culture. For example, Marx classified cultures into modes and structures, such as primitive communist, feudal, and capitalist.

The German American historian and playwright Karl Wittfogel (1959) built on Marx’s theory in his “hydraulic hypothesis,” started from the observation that Asian countries such as China and Japan had strong despotic governments. Wittfogel explained this using Marx’s emphasis on the mode of production. Wittfogel argued that India and China relied on large-scale irrigation, which lent itself to large forced-labor projects. Since only a strong, centralized power could coordinate these programs, many

societies in Asia developed into despotic empires. However, more recent scholars have argued that Wittfogel got some of the basic facts wrong. For example, most irrigation networks in China were coordinated at the village level (Bray, 1986; Elvin, 2008).

Although Marx is no longer mainstream, modern subsistence theories also focus on how societies made a living (Nisbett, Peng, Choi, & Norenzayan, 2001). In the tradition of materialism, anthropologist Marvin Harris (1977) studied how culture grew out of a response to environmental pressures. For example, he explained cannibalism in Aztec culture as a response to protein deficiency. He explained the Muslim prohibition on pork partly as a response to the fact that pigs root through the soil, which damaged the fragile soils in Israel and the Middle East, where the prohibitions originated (Harris, 1975). He also argued that this could explain why Islam spread to the drier parts of western China, but not the wetter parts of eastern China, where the environment can support pigs.

It is important to understand these earlier ecological theories in the context of the time. Harris was arguing against researchers who believed that culture is a reflection of genetic selection or inborn traits. For example, when Harris was explaining the war-like culture of the Yanomamo people of South America, he was arguing against people who thought this ferocity was genetic.

Ecological anthropologists such as Harris were in the middle. They rejected earlier biological anthropology that saw cultural differences as inborn or entirely genetic. At the same time, they rejected symbolic anthropology, which views culture as a primarily or exclusively human construction.

Early Psychological Studies of Ecology

Against this backdrop, some early psychologists started studying culture as a response to the environment. One series of early ecological studies in the 1960s tested whether growing up in different physical environments affected people's visual perception (Segall, Campbell, & Herskovits, 1963). Researchers tested European Americans and 12 populations in Africa on common visual illusions like the Müller-Lyer illusion (Figure 4.1). They

found that European Americans and European South Africans were more susceptible to the illusion than some of the other African populations.

FIGURE 4.1. The Müller-Lyer illusion. To most people, the bottom line appears shorter than the top line, but they are both the same length. Researchers have found that European Americans are more susceptible to this illusion than people from several traditional African communities.

Psychologists thought of these illusions as fundamental, so why would people in different cultures be less susceptible? The researchers argued that Europeans were more susceptible to the illusion because they live in environments with more right angles—for example, the corners of modern rooms. The sorts of acute and obtuse angles in [Figure 4.1](#) condition people to infer a three-dimensional rectangular space, which leads to the illusion (Segall et al., 1963, p. 770). In contrast, people living in homes without modern carpentry or who spend more time outdoors do not see as many of these carpentered right angles. Thus, they are less likely to infer a three-dimensional rectangle.

However, this does not mean that people in more natural environments are always better at perceptual illusions. Americans were less susceptible to the horizontal-vertical illusion ([Figure 4.2](#)). The researchers hypothesized that the horizontal illusion is caused when viewers subconsciously infer that the vertical line extends away from them in the visual field. That sort of inference would be more common for people living on open plains. In sum, there is some evidence that our physical environments affect even something as basic as a subconscious visual illusion.

FIGURE 4.2. The horizontal–vertical illusion. To most people, the vertical line appears longer than the horizontal line, but they are both the same length. Researchers have found that European Americans are less susceptible to this illusion than people from several traditional African communities.

Early Subsistence Theories

One major line of ecological theories is subsistence theory. Subsistence theories argue that the way people in a culture make a living—hunting and gathering, fishing, herding—influences their culture. In the 1950s and 1960s, researchers ran studies testing whether food accumulation is important for culture (Barry, Child, & Bacon, 1959; Berry, 1967). Farmers accumulate and store food because harvests are not spread out evenly through the year. In contrast, some hunter–gatherer and fishing cultures have more steady sources of food throughout the year.

Barry and colleagues (1959) argued that cultures that accumulate food are more interdependent, because they have to decide how to distribute the harvest throughout the rest of the year. Berry (1967) tested how much people conformed to other people’s answers, even when those answers were obviously wrong on the Asch (1956) social conformity task (Figure 4.3). He tested Temne farmers in Sierra Leone (who accumulate food) and Inuit hunters in northern Canada (who accumulate less food). Consistent with the theory, the Temne farmers conformed more than Inuit hunters.

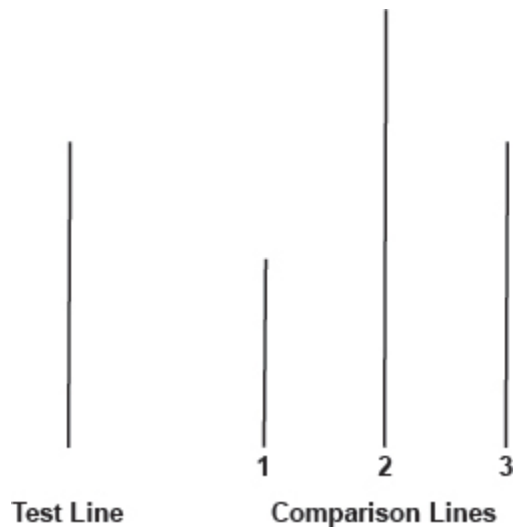

FIGURE 4.3. In Berry's adaptation of the Asch social conformity task, participants have to say which comparison line is the same length as the test line. However, on some trials, participants learn that others in their group have chosen the incorrect answer. The key measure is the percentage of participants who follow others' incorrect answers.

The anthropologist Walter Goldschmidt (1971) tested a different version of subsistence theory that was not about food accumulation. He argued that the work of farming is more interdependent than herding. First, herders do not depend on other people to complete their work as much as do farmers. Second, herders move around a lot. This gives them more options for avoiding other people: "When conflict arises, they find it possible simply to move away from it" (Goldschmidt, 1971, p. 135). Because farmers are tied to their fields, they cannot just move away from conflict.

To test this idea, Goldschmidt studied people in four East African tribes that all had subgroups that herd and farm (Edgerton, 1965, discusses the design of the study). He found that herders were far more independent than farmers, even though they were from the same tribe. By testing people in the same tribe who differ on farming and herding, Goldschmidt could help rule out variables that make it hard to compare two different cultures, such as language and religion.

MODERN ECOLOGICAL STUDIES

Researchers have continued to test ecological theories in modern times. In *Guns, Germs, and Steel*, Jared Diamond (1997) proposed a complex ecological theory of European civilization. He outlined how Eurasia's temperate climate and fertile soil gave rise to food surplus and plenty of domesticable animals early on. Over time, this gave Eurasian civilizations an advantage by providing food sources (e.g., chicken), military force (e.g., horse), and health (e.g., resistance to viruses). In Diamond's view, these factors helped Europe dominate the world after the end of the Medieval Period.

Modern Subsistence Theory

One stream of research in the last 20 years has picked up the tradition of subsistence theory. Nisbett and colleagues summarized dozens of findings of cognitive differences between the East and West and argued that these differences stem from traditions of farming in the East and a mix of hunting, herding, fishing, and trading in the West (Nisbett, 2003, p. 34; Nisbett et al., 2001). They argued that the West's—and particularly Ancient Greece's—history of herding has given the West a more individualistic culture. In contrast, farming made up a bigger part of subsistence in East Asia, and farming leads to enmeshed, tight relationships.

Methodological Issue: How Can We Test for Causality?

At this point, savvy readers will notice a problem. How can we be sure of our explanations for differences between large cultural blocs such as the East and West? There are lots of differences between East and West—development, language, religion, and warfare, to name a few. How can we know that farming and herding made any difference to these cultures?

Cultural psychologists are limited, because we cannot run true experiments. We cannot randomly assign one culture to herd for thousands of years and another culture to farm for thousands of years and see what happens. This prevents us from attaining the “gold standard” certainty of causality.

However, cultural psychologists do have other tools that can get us closer to causality. One common tool is controlling for third variables in regression analysis. Another tool is natural experiments. If we can find nearby areas that are similar on most variables but different on the variable we are studying, we can get a stronger test of whether that variable affects culture.

Uskul, Kitayama, and Nisbett (2008) found a natural experiment in Turkey. They tested people in adjoining villages who share linguistic and cultural backgrounds. However, they differ in how they make a living—some farm, others fish, and still others herd. They found that people in the farming and fishing communities had a more holistic cognitive style (more common in collectivistic cultures), whereas the herders had a more analytic cognitive style (more common in individualistic cultures). This type of controlled case study offers more precise evidence that differences in subsistence style can cause differences in psychologies.

Most tests of subsistence theory have compared completely different styles, such as herding versus farming. Talhelm and colleagues (2014) tested whether different forms of farming can produce different cultures. Not all types of farming are the same. We tested whether Han China's rice-farming south has a different psychological culture from the wheat-farming north ([Figure 4.4](#)).

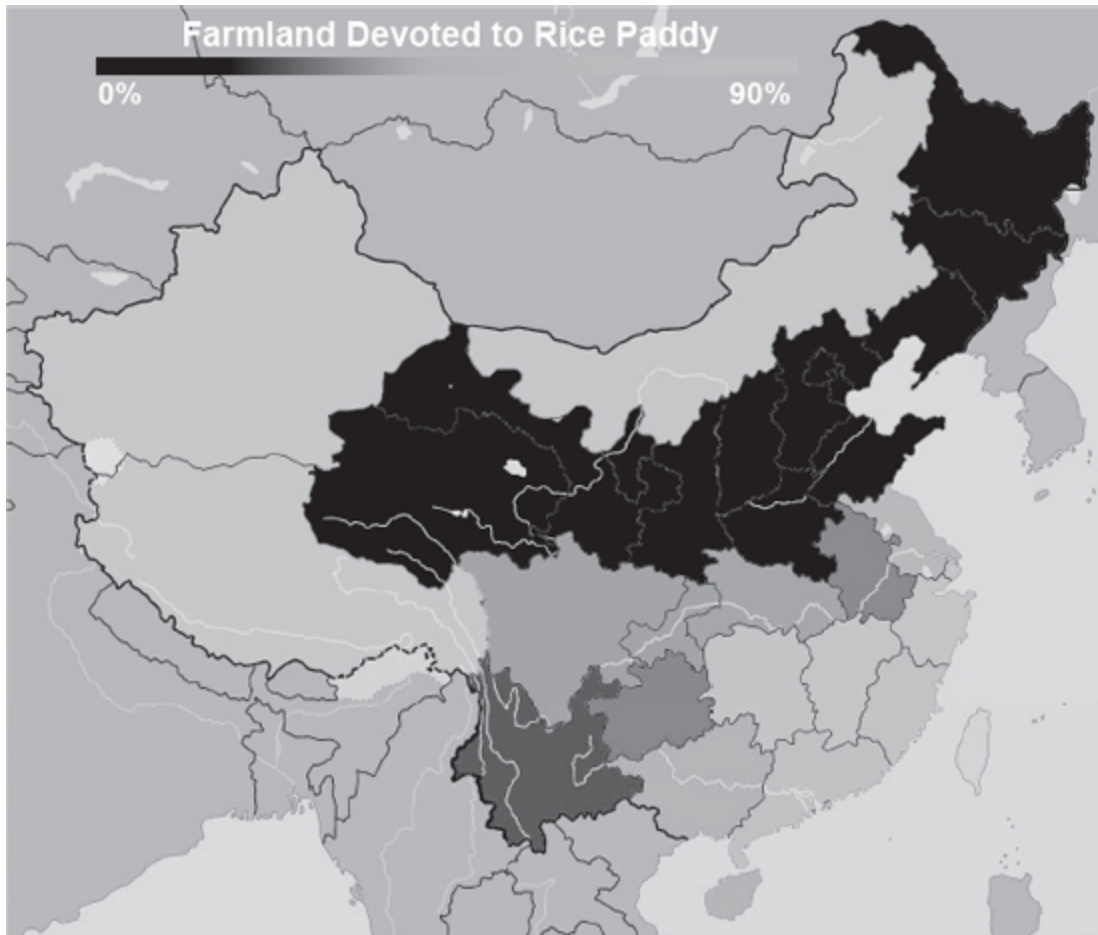

FIGURE 4.4. Percentage of farmland devoted to rice paddies per province in China. Statistics are from the 1996 Statistical Yearbook. Southern China has a history of farming rice, and its culture has tighter, more enmeshed relationships compared to the relatively loose culture of China's wheat-growing north.

Why is rice farming so different from wheat farming? First, traditional paddy rice required about twice the number of man-hours per acre as crops like wheat (Fei, 1945, p. 214). Second, rice farmers often built irrigation networks, which forced farmers to coordinate when they filled and drained their fields.

In contrast, wheat farming required about half the number of hours of work, and wheat farmers usually relied on rainfall. This means wheat farmers had less need to work together; rain falls whether families cooperate or not. Thus, wheat farmers had more freedom from their neighbors than rice farmers.

We found that Chinese students who had grown up in rice provinces were more interdependent and holistic thinking than students from wheat provinces (Talhelm et al., 2014). There were even cultural differences in neighboring counties along the rice–wheat border in central China. Even though counties along this border mostly shared government, ethnicity, and religion, the different environments pushed the north and south toward different crops and different cultural styles.

Alesina, Giuliano, and Nunn (2013) analyzed another distinction between different types of farming—whether farmers planted crops that required heavy plows or not. Crops such as wheat, barley, rye, and paddy rice usually grow best in plowed fields, and people who grow these crops use heavy plows. Much of Western Europe and North America has a climate and soil suited for plow crops such as wheat. In contrast, crops such as millet, corn, and sorghum can thrive in fields that are only lightly raked or hoed. Drier areas, such as Botswana, Kenya, and Tanzania in south central Africa, have a hard time growing wheat and barley, but they can grow non-plow crops such as millet.

This is important for culture, because plows require significant upper-body strength, which is one of the largest biological differences between men and women. Thus, plow cultures developed a starker division of labor between men (who could plow) and women. But this division was not so stark for cultures that farmed crops such as millet, which do not require so much upper body strength. Thus, women and men could contribute more equally to farming.

Alesina and colleagues (2013) found that cultures' history of plow use affected women's position in society. Plow cultures—even in the modern world—have lower rates of female labor force participation, fewer female entrepreneurs, and fewer females in government. In the World Values Survey, people in plow cultures are more likely to say that men and women should have different roles in society.

The differences are particularly surprising among poor countries. It is intuitive to think that poor countries have traditional views on gender equality, but there were stark differences even between cultures with developing economies. For example, in Pakistan (a plow culture), 16.1% of women work; in Burundi (non-plow culture), 90.5% of women work.

One theme that runs through subsistence theory is the surprising finding that elements of our past can continue to affect our behavior today, even long after most people have put down their plows and moved to office jobs. One extreme example comes from Nisbett and Cohen's (1996) study of the U.S. South's culture of honor. They built on a study of immigration to the original U.S. colonies, showing that the Appalachian South was settled by people from herding cultures like the Scots-Irish. In contrast, the Yankee northeast was settled by English farmers and middle-class craftsmen (D. Fischer, 1989).

Nisbett and Cohen (1996) argued that herding influenced the South's attitudes toward violence and honor. Why? One thing that makes herding different from farming is that herders' property is easy to steal. Cows and sheep are incredibly valuable, and thieves can steal them in the time it takes their owner to nap. In contrast, fields of wheat and rice take hours and hours of hard work to harvest. Farmers did not wake up in the middle of the night to find thieves harvesting their wheat.

If herders have stealable property and live in an area without adequate law enforcement, they must present a credible threat to thieves. Toughness is more of a cultural virtue in herding cultures. This is what Nisbett and Cohen (1996) found when they tested people from the South and the North. For example, they sent fake resumes to companies in the North and South, in which the applicant admitted to killing someone. Yet the applicant explained that the deceased had had an affair with his wife (a classic affront to honor), and he had served his jail time. Southern companies were more likely than northern companies to respond to the applicant.

In another study, the researchers arranged for a confederate to bully a participant and see whether the participant would confront him. Participants came to the lab and started drawing pictures as a part of a study. The confederate then began annoying the participant in a series of scripted steps. He called the participant "slick," wrote this new nickname on the participant's paper, and even crumpled up his paper, threw it toward the waste basket, and "accidentally" hit the participant. The Southerners were more likely to take the abuse quietly at first, then explode in anger; northerners were more likely to argue at first, then take the rest without fighting back.

Finally, Nisbett and Cohen (1996) analyzed public data on violence. They found higher rates of honor violence in the South, such as shootings based on an argument or an extramarital affair. However, there were no differences in non-honor killings, such as killings during robberies.

Although these studies have provided evidence that places with different historical subsistence styles have different cultures, one limitation is that most studies compare two cultures. Henrich and colleagues (2005) scaled up subsistence theory by testing more cultures and trying to abstract the general principles of subsistence across cultures. Instead of comparing, say, farmers and herders, they tested people from 15 small-scale societies around the world, from Polynesian whale hunters to nomadic foragers in Tanzania. They had people in each society play standard economic games such as the ultimatum game (Figure 4.5).

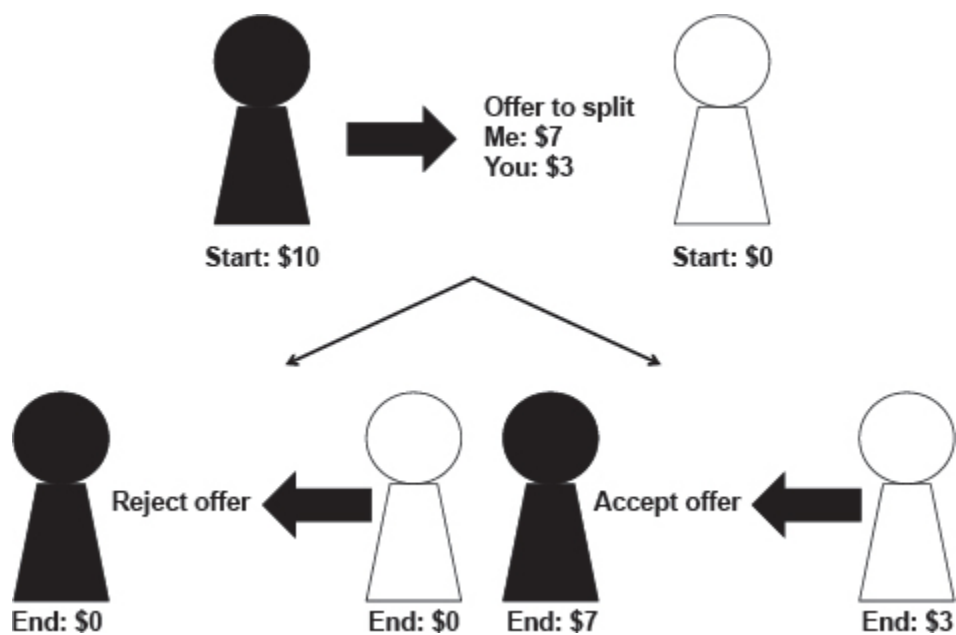

FIGURE 4.5. In the ultimatum game, one participant starts with \$10 and has to decide how to split it with another player (completely selfish = 10–0; completely equal = 5–5; completely generous = 0–10). The other player can accept or reject the offer. If the receiver rejects it, both people receive nothing.

To measure subsistence style, researchers ranked the different cultures on variables such as market integration. They focused on market integration, because dealing in markets gets people accustomed to making exchanges

with strangers, thereby building norms of cooperation with strangers. They found that people in societies with more market exchanges were more likely to make generous offers to strangers in the ultimatum game. Furthermore, cultural-level variables (whether a culture had lots of market interactions) explained far more variance in people's behavior than individual-level variables (such as whether a person participates in market exchanges or not).

Reverse Causality: Are Cultural Practices a Response to the Environment?

One question that runs through many studies of culture and environment like these is reverse causality. For example, think of the independent herders and collectivistic farmers that Goldschmidt studied in Africa. Maybe one group was more independent in the beginning, so they decided to start herding because it fit their values. And maybe the other groups were already more collectivistic, so they decided to become farmers. If so, the subsistence style is not changing the culture. Instead, their culture is determining what subsistence style they choose.

Goldschmidt (1971) argued against this interpretation. He wrote that independence is “not merely a matter of personal choice, but is necessitated by environmental circumstances—i.e., it is an ecological adjustment” (p. 136). Most socioecologists similarly argue that cultural practices such as farming usually depend on the activity that is the most productive in different environments and not what people *want* to do, as if they were choosing from a menu of lifestyles in a restaurant. People generally adapt to their local environment to maximize the payoffs.

One way to test this question is to analyze the climates in different areas of the world to see which types of farming are possible in different areas. In their study of plow use, Alesina and colleagues (2013) used a climate database from the United Nations Food and Agriculture Organization to test which areas of the world have the climate to grow plow-suitable crops (such as wheat, barley, rye, and paddy rice) versus non-plow crops (such as millet, corn, and sorghum). Using this method, they can test whether a non-

human-controlled variable (climate) is related to cultural practices. If so, it is unlikely that human choice (reverse causality) is the key factor.

Similarly, in our study of rice and wheat in China, we analyzed climate statistics to determine whether China's rice and wheat regions were determined by what people *wanted* to plant versus what they *could* plant (Talhelm et al., 2014). In theory, farmers should plant paddy rice if they can, because it produces far more calories per acre than crops such as corn and wheat (Bray, 1986). For example, researchers in the 1930s found that Chinese rice farmers were producing 223 kilograms of rice per 666.5 square meters. Wheat farmers were producing 141 kilograms. Thus, places that have the right environment to plant paddy rice "should" be planting paddy rice.

This is what actual farming data showed in China. The potential to grow rice on farms was correlated very highly with actual rice production ($r = .85$, $p < .001$). Thus, rice farming in China seems to be more consistent with maximizing payoffs based on the environment rather than people choosing the crops they want to farm.

However, we should not pretend that climate is simple. One type of climate can support many different patterns of living, and those styles can change over time. For example, modern-day California can produce many types of crops, such as broccoli, grapes, and even rice. But over the last few years, the price of almonds has gone up, and farmers have been ripping out other crops to plant more almonds (Smith, 2015). Even in a single climate, farmers can grow different crops. Climate constrains production, but it does not completely determine a single crop that must be planted.

Controversy: Is Ecological Psychology Ecological Determinism?

In the discussion of how the environment shapes culture, it is easy to make oversimplifications. People who are wary of these oversimplifications have sometimes accused ecological theories of "ecological determinism," which is the extreme view that the environment completely determines culture. In the extreme, we would say, "If you have X environment, you necessarily have

Y culture.” If Brazil and Cambodia both have rainy, humid environments, they should have exactly the same cultures.

One reason “ecological determinism” is a dirty name is that oversimplified ecological theories rob humans of agency. If the external environment determines what sort of culture we have, then humans are passive cogs in a machine. And if so, is there any room left for humans to interpret their world through things such as religion and philosophy? Surely, the environment is not everything.

However, ecological theories need not be so deterministic. Virtually all cultural psychologists would agree that many factors influence culture. The environment is one factor among many—cultural sharing, genetics, and technology, to name a few.

Another way to say this is that different cultures can arise from the same environment. Even in a single environment, cultures change how they interact with that environment over time. For example, in the early 1900s, Americans discovered large oil deposits in Texas, and a massive drilling boom started (Olien, 2010). That boom peaked in the 1970s, and it shaped the Texas economy. But eventually, oil production shrank to a small portion of its former size (Olien, 2010).

However, that did not mean all the oil was gone. The ground had a lot more oil in it, but it was too hard to get out of the ground. All of that changed in the 2000s, when the new hydraulic fracturing technique (fracking) allowed drillers to get to that locked up oil. Thus, even with a fixed amount of oil under the ground, technology has changed how humans have used that oil over time.

Cohen (2001) has described how very different cultures can grow, even in similar environments. For example, he argued that people’s decisions about whether to trust other people depend on the dominant social norm in an area. If people tend to violate trust, newcomers are pushed toward using the same strategy. That can lead cultures to a stable equilibrium that is hard to break. Thus, a single environment could host a trusting culture or a low-trust culture, depending on the norms of the settlers and the institutions they build (Cohen, 2001, p. 457).

For that reason, most ecological psychologists hold a more nuanced version of ecological theories. One way to formulate this more nuanced version is that different environments present opportunities and problems,

and people can respond to these problems in different ways. However, some responses may be more common than others, and these encourage similar cultural adaptations.

One way to illustrate this “environments present problems” version of the theory is through China’s rice farming. The ecological determinism version of the rice theory is to say that rice farming causes cultures to be collectivistic. But Talhelm and colleagues (2014) explain how the theory is actually more complicated. Irrigated paddy rice presents a problem: It requires more work than many other staple crops (Buck, 1935).

Lots of different cultures have farmed rice, but they have solved the labor problem in different ways. One of the most common ways to solve the problem was to form cooperative labor exchanges. Rice farmers in China, Japan, Malaysia, and Sierra Leone helped farm each other’s fields during peak labor times (Bray, 1986; Richards, 1987).

But people in other cultures solved the problem differently. Some U.S. landowners in Southern states such as Georgia “solved” the problem by forcing slaves to plant the rice. And in modern times, farmers in Australia have used diesel plows and even airplanes to seed their rice fields. Even though all of these areas had the right environment for rice, they built different cultures around it.

ENVIRONMENTAL CHALLENGES

Disease

The environment’s capability to support rice farming or herding may be thought of as an opportunity, but environments also present challenges. One series of studies has focused on pathogen prevalence, the frequency of diseases in different areas. Tropical environments have high pathogen prevalence, but dry and cold climates are too harsh for many diseases, and so they have lower pathogen prevalence. Areas that freeze in the winter have some of the lowest rates, because freezing temperatures kill many types of bacteria.

Several researchers hypothesized that pathogen-rich environments would make people more collectivistic and more likely to shun outsiders,

because outsiders are more likely to be a germ threat (Fincher, Thornhill, Murray, & Schaller, 2008); in fact, countries with higher disease prevalence rates score higher on measures of collectivism. Regions with higher disease prevalence score lower on extraversion, openness to experience, and open sexual behaviors (Schaller & Murray, 2008).

A team of economists took a different approach to disease (Acemoglu, Robinson, & Johnson, 2003). From the 1600s through the 1800s, Europeans colonized many parts of the world. Yet some of those environments were extremely inhospitable to Europeans. For example, a British committee deciding where to send convicts considered a site on the Gambia River in West Africa, but they decided against it, because the mortality rates for Europeans there were too high—even for convicts.

The researchers argued that mortality rates were important for culture, because mortality rates affect what type of colonies the Europeans set up. When Europeans found they could live and survive in a region, they tended to establish settler colonies with more infrastructure and institutions. When Europeans found it hard to settle and survive in a region, they tended to neglect institutions and instead set up short-term extractive economies (for example, mining gold).

The economists found that this historical legacy persists into the modern day (Acemoglu et al., 2003). Countries that had high European mortality rates in the past now have far lower gross domestic product (GDP) per capita than countries in which Europeans could survive. Their study suggests that the environment was important in determining whether colonies set up functioning institutions.

The difference between how the economists and psychologists approached the same problem is an interesting example of how the two disciplines tend to think of cause and effect. The psychologists focused on psychological adaptations to disease—xenophobia and low extraversion. The economists focused on external institutions—extractive industries that are not conducive to market economies and democratic representation. Researchers in both fields looked at how disease affects human culture, but they came up with very different mechanisms to link disease and modern culture.

Natural Disasters

Natural disasters such as earthquakes and floods are another type of challenge that cultures face. Gelfand and colleagues (2011) hypothesized that natural disasters tend to create chaos, so cultures that frequently face natural disasters try harder to maintain order. These cultures punish people more harshly for deviant behavior and have stronger social norms. They also theorized that other threats would push cultures to enforce tight social norms—resource scarcity, high population density, diseases, and invasions. In contrast, when people are in safer environments, they are more flexible and tolerant of different behaviors.

To test the theory, they asked people in 33 nations to rate how acceptable different behaviors were in different situations. For example, how acceptable is it to eat in a bank, on the sidewalk, or in the workplace? How acceptable is it to flirt in a public park, in a classroom, or at a funeral? Cultures with higher rates of natural disaster had more restrictions on people's behavior ($r = .47, p = .01$; Gelfand et al., 2011).

Other researchers have studied the opposite perspective: What happens when cultures develop in safe, fertile regions? Galor and Özak (2014) found that areas with high potential crop yield before 1500 tended to have cultures with long-term orientation. They were more oriented toward future rewards, perseverance, and thrift. The main idea is that if the natural environment is benevolent and predictable, people who live in that environment benefit from making long-term plans. Yet when disasters strike and wipe out the resources that people have built up, it is harder to maintain a long-term strategy.

FRONTIERS

Frontiers are another type of environmental challenge. Remoteness means that state institutions often play a smaller role in frontiers. People living in dense areas can rely on police departments and courts to resolve disputes, but people in frontier areas more often have to solve problems without formal institutions. In a sense, people in frontiers were freer, but they missed out on some of the benefits of centralized governments (Scott, 2014).

Kitayama and colleagues (2006) tested Japan's northern frontier, Hokkaido Island. Although Hokkaido was inhabited with indigenous Ainu people, ethnic Japanese people started settling the island in the late 1800s. Settlers faced a harsher, colder climate and a sparse population.

They found that Hokkaido residents were more individualistic than people in other parts of Japan. For example, Hokkaido residents were more likely to associate happiness with personal achievement, as opposed to social reasons such as feeling close to others. They were also more likely to explain people's behavior based on internal factors (such as personality) rather than external factors (such as social pressure).

Kitayama and colleagues (2010) also argued that frontiers shaped individualism in the United States. Researchers have found that some U.S. states are more individualistic than others. They ranked states on individualism, based on indicators such as self-employment, living alone, and divorce rates (Vandello & Cohen, 1999). Most Western states (such as Colorado and Wyoming) are among America's most individualistic states. Kitayama and colleagues argued that the frontier environment could explain these differences.

Another team of researchers tested the frontier theory from a slightly different angle (Conway, Houck, & Gornick, 2014). First, they measured two types of terrains that are more likely to make areas less hospitable and more of a frontier—mountains and inland terrains. Mountains make travel harder, and they often have unpredictable weather. Inland terrains are far away from the nearest ocean or great lake. Water was by far the most efficient form of transportation before trains, planes, and cars (Scott, 2014). Being far away from water transportation made inland areas more isolated.

Next, they tested whether mountainous and inland U.S. states were more individualistic on Vandello and Cohen's (1999) individualism index and lower on a measure of legal restrictions (such as gun laws and traffic rules). They found that U.S. states that were farther inland were more likely to be individualistic on both measures. Mountainous states had less restrictive laws, although they did not score higher on the individualism index. They found similar results when they used the same measures in a sample of over 70 nations around the world.

Fearon and Laitin (2003) argued that mountains have another effect—they make civil wars more likely. Mountains can support rebellion because

they are sparsely populated and because governments have a hard time building roads and exerting their influence there (Scott, 2014). This makes rebel groups more likely to succeed in mountainous areas.

Fearon and Laitin (2003) framed their argument against a common explanation for civil wars. Many people have blamed ethnic and religious divisions for the bloody civil wars of the 20th century. However, Fearon and Laitin analyzed civil wars from the 1950s through 2000 in the massive Correlates of War database, and found that ethnic and religious diversity did not predict civil wars. But consistent with their hypothesis, mountainous areas were more likely to have civil war.

The Wealth Buffer

If the environment presents a challenge, wealth often provides a way to deal with that challenge. Similar to Gelfand and colleagues' (2011) argument about environmental threats, Van de Vliert (2007) argued that harsh climates make cultures less accepting of self-expression. Van de Vliert measured harsh climates by temperatures hotter or colder than 22°C (72°F). However, Van de Vliert took this idea a step further by saying that this relationship weakens or disappears in wealthy countries. Wealthy countries can use wealth to protect themselves from the climate. For example, wealthy Singaporeans live in air-conditioned homes and shop in air-conditioned malls.

Van de Vliert (2007) tested whether wealth could buffer the effect of climate on self-expression. Replicating Gelfand and colleagues' (2011) theory, he found that countries with harsher climates are less accepting of self-expression. But in line with the buffer theory, among poor countries, places with harsh climates were less likely to support self-expression values. Among wealthy countries, the climate made no difference.

Van de Vliert (2009) found a similar pattern in the relationship between climate and life satisfaction. People are generally happier in countries with comfortable climates (around 22°C or 72°F). In less-developed countries, this relationship is strong; people are less happy in places that are too hot or too cold. But the climate mattered a lot less for people in wealthy countries. Results were similar when they analyzed anxiety, depression, job burnout,

and health complaints as the dependent variables (R. Fischer & Van de Vliert, 2011).

Physical Environments

Nunn and Puga (2012) analyzed how treacherous physical environments may actually be a good thing. This is counterintuitive, because rugged environments are usually bad for the economy. Mountains, swamps, and waterfalls make it harder to build roads and ship goods, which means that rugged areas tend to be poorer than accessible areas (Nunn & Puga, 2012, p. 23).

However, Nunn and Puga (2012) found that Africa is an exception to the ruggedness rule. Why? From 1400 to 1900, the slave trade devastated Africa. But rugged areas were partly spared, because it was not efficient to move slaves through these regions. Slave traders mostly avoided mountainous areas. Unlike the rest of the world, Nunn and Puga found that rugged African countries have *better* economies nowadays. This was particularly true for West Africa, where the slave trade was the most severe.

Psychologists studied another type of physical environment that is closer to modern life—the urban environment (Miyamoto, Nisbett, & Masuda, 2006). They started with the decade of research in cultural psychology, finding that Easterners and Westerners have different perceptual styles. For example, when looking at the same pictures or websites, Westerners tend to spend more time looking at the main objects (such as a ram in front of a mountain; see [Figure 4.6](#); Masuda, Russell, Li, & Lee, [Chapter 8](#), this volume; Masuda & Nisbett, 2001; Dong & Lee, 2008). In contrast, people in East Asia tend to split their time more evenly between the central object and the background.

FIGURE 4.6. In studies of scene perception, Westerners tend to spend more time looking at the focal object, here the ram. People in China and Japan also look at the focal object, but they spend more time than Westerners looking at the background. From Masuda and Nisbett (2001). Copyright © 2001 the American Psychological Association. Reprinted by permission.

Miyamoto and colleagues (2006) had the idea that the built environment in the East and West might reinforce these perceptual differences. Miyamoto noticed that Japanese cities simply have more objects to look at, more stuff going on. In contrast, American cities were “cleaner,” with fewer things to look at. She hypothesized that exposing people to these city environments in Japan and the United States could activate the two styles of perception.

To test the hypothesis, Miyamoto and colleagues (2006) first tested the base assumption that Japanese cities are more complex. They collected pictures of small, medium, and large cities in the United States and Japan, then they used a computer program to quantify the number of objects in the environment—the more objects, the more complex the scenes. As they predicted, the Japanese environments were more complex than the U.S. environments.

Next, they showed people pictures of Japanese and American cities, and tested their perceptual style. Sure enough, showing both American and Japanese participants the complicated Japanese scenes increased their attention to the contextual details. Showing them the more simple American scenes increased their attention to focal objects. This suggests that people’s physical environments can encourage different types of perceptual styles.

HUMAN ENVIRONMENTS

The buildings, streets, and parks we live in are an obvious type of environment. However, psychologists have also argued that we live in a human environment, too—the people around us. Psychologists have studied how that human environment affects our behavior.

Population Density

One simple measure of the social environment is how many people there are around us. Milgram (1970) developed the “overload hypothesis” to understand how population density affects us. He argued that people in dense urban environments see so many people every day that they need to conserve their energy and limit the number of people they interact with. This may explain the popular perception that people in big cities are cold, whereas people from small towns are nice and willing to help strangers.

Researchers have also argued that population density can make cultures collectivistic (Kitayama et al., 2010, p. 566; Triandis, 1995, pp. 58–59; Triandis, 2001). The reasoning is that if we live around lots of other people, we have to learn how to get along with them and grow accustomed to other people. If we live in places with few people, we have more land to ourselves, and we do not have to interact with other people.

Although the logic seems intuitive, some studies have found support for the density theory, and others have not. In a study in the United States, Vandello and Cohen (1999) found that densely populated states are more collectivistic, but it was not significant ($r = .22$, $p = .12$), although the percentage of population in urban areas did significantly correlate with collectivism ($r = .38$, $p = .01$). A study across countries found no significant correlation between density and four measures of conformity ($ps > .25$; Murray, Trudeau, & Schaller, 2011). At the very least, the link between population density and collectivism remains unresolved.

Rather than looking at collectivism per se, Gelfand and colleagues (2011) theorized that population density would be related to situational tightness. They argued that historical population density was a survival pressure, because density would have made famines more acute and disease

more common. In response, these cultures have tighter restrictions on people's behaviors (for example, it is less acceptable to hold hands in public or eat in a classroom). In line with this prediction, areas with high historical population density had tighter situational constraints ($r = .77, p < .01$).

Ethnic Diversity

Another type of human environment is ethnic diversity. Researchers argue that historical diversity affects how people express emotions (Rychlowska et al., 2015). They argued that expressing emotions more clearly helps people communicate with those from other cultures. As an extreme example, if you meet someone from a different culture who speaks a different language, you might start using exaggerated facial expressions to get your meaning across. But in cultures that are more homogenous, people can rely on shared understandings of expressions and the meaning of situations, and thus they do not need to rely on explicit emotional expressions.

To measure ethnic diversity, the researchers used the number of countries modern-day residents can be traced back to. For example, people living in the United States today can be traced back to 83 countries in 1500 C.E. Canadians can be traced back to 63 countries. The Japanese can be traced back to only one country, a single major wave of immigration. In a large cross-cultural survey, people from diverse countries such as the United States and Canada were more likely than people in less-diverse countries such as Japan to say it is OK to express emotions such as anger, happiness, and sadness in a variety of situations. Cultures that were historically settled by people from many cultures are now more emotionally expressive.

Researchers have also tested whether ethnic diversity causes social conflict. For example, a team of economists found evidence that ethnic diversity can reduce how much different countries provide in public goods (Alesina, Baqir, & Easterly, 1999). They found that diverse neighborhoods, counties, and cities in the United States spend less on public goods such as schools, roads, and libraries. This relationship held even when comparing areas with similar levels of wealth.

Similarly, Robert Putnam (2007) argued that ethnic diversity causes "hunkering down." He found that more diverse areas of the United States

have lower social capital. People in diverse areas tend to trust each other less (even people of the same race). They are also less likely to donate to charity and to believe that other people will cooperate to solve common problems (such as voluntarily using less water to ease a water shortage).

This argument has caused controversy, particularly among liberals, who often celebrate diversity (Jonas, 2007; Sturgis, Brunton-Smith, Read, & Allum, 2011). However, Putnam (2007) did not say diversity is always a curse. He pointed to cases in which organizations became more diverse and stronger, such as when the U.S. army became racially integrated. In the long run, he argues that diverse societies can overcome the “hunkering down” response and create new forms of identity that include more people. For example, Americans who used to identify as German or Irish now often identify simply as Americans.

Residential Mobility

Another characteristic of the social environment is residential mobility—how frequently people move. Some cultures encourage people to move more, whereas others encourage people to stay in one place. For example, universities in the United States rarely allow their own undergraduates to stay on for their PhD at the same university. Instead, most American researchers believe that going to a different university will help students by exposing them to different perspectives. In contrast, it is more common for undergraduates to stay in the same school for their PhDs in countries such as Germany and Japan. The cultural endorsement of moving could explain why 50% of Americans move at least once every 5 years versus 28% in Japan (Oishi, 2010).

Researchers have explored how these different rates of mobility affect culture (for a reviews, see Oishi, 2010; Oishi & Talhelm, 2012). One finding is that people in communities with high mobility tend to identify with groups conditionally (Oishi, Ishii, & Lun, 2009; Oishi et al., 2007). If the group identity is beneficial, movers are more likely to identify with the group. If it is not beneficial, they are more likely to dissociate from the group.

One study tested this idea by having students at the University of Virginia read an article that ranked it as the top U.S. public university (Oishi et al., 2009). Students in another condition read an article reporting that Virginia had just lost its #1 spot. After the article, researchers asked the students how much they identified with the school. Nonmovers tended to identify with the university regardless of the ranking, but mobile students were less likely to identify with the university if it was no longer #1.

That study measured individual moving, but moving can also be a characteristic of a community. Mobility can change the culture of a community, even for people who themselves have not moved. In the same way, a history of rice farming or herding can affect people's behavior, even if they do not farm rice or herd cattle themselves (Nisbett & Cohen, 1996; Talhelm et al., 2014).

Mobile communities tend to support community causes less. For example, people in mobile neighborhoods in Minnesota were less likely to buy "critical habitat" license plates that give a portion of money to protect natural areas (Oishi et al., 2007). Baseball teams in mobile U.S. cities had more "fair weather fans" who stop attending games when the team is having a bad season (Oishi et al., 2007). Although Japan has lower mobility than the United States, baseball fans in mobile Japanese cities like Fukuoka had more fair weather fans than teams in less mobile cities such as Osaka (Oishi et al., 2009).

Mobility can also alter the friendship strategies that make people happy. If the people around you are likely to move away, it makes sense to diversify your friend investment and have a broad but shallow friend network. That way, even if a friend moves away, you still have many other friends to fall back on. However, if the people around you are likely to stay in the same place, you can invest more time in a small group of tight friends. Those sorts of deep ties are particularly useful when we need help.

Oishi and Kesebir (2012) tested this by asking people around the United States about their friendship strategy. In general, people who had a broad but shallow strategy were happier, which is consistent with the fact that the United States is a highly mobile culture. But people in low-mobility communities—particularly communities with struggling economies—were happier if they had a narrow and deep strategy.

Relational Mobility

Later researchers extended the concept of residential mobility to relational mobility (Schug, Yuki, & Maddux, 2010; Yuki & Schug, 2012). “Residential mobility” is how often people move; “relational mobility” is their perception of how easy it is for people in the community to make new friends and leave old friends. Thus, two communities could have the same residential mobility rate but different perceptions of how often people move between relationships.

One study found that relational mobility could explain why Americans share personal information with new people so easily and why people in Japan are much more reluctant to share personal information (Schug et al., 2010). Sharing personal information helps create new relationships, and Americans may be in the habit of sharing personal information so easily because they start new relationships so frequently. In contrast, Japan’s low relational mobility could explain why people in Japan tend to share less personal information. Schug and colleagues found that people who see their community as relationally mobile are more likely to want to share personal information.

More recent studies have found that relational mobility can explain cross-national differences in how well self-esteem predicts life satisfaction (Yuki, Sato, Takemura, & Oishi, 2013; Sato & Yuki, 2014). In the US, people with high self-esteem were much more satisfied with their life than people with low self-esteem ($b = 0.70, p < .001$). In Japan, people with high self-esteem were also happier, but the relationship was less strong ($b = 0.45, p < .001$). In addition to self-esteem, social relationship quality predicted how happy Japanese people were, but not for Americans.

The researchers argue that societies with high relational mobility act like free markets, and people with high self-esteem (high social worth) can use that worth to go out and acquire satisfying relationships. In contrast, in countries with low relational mobility, people tend to form committed relationships that are not so affected by people’s market value. Because the social relationship market is not a free market, it is hard to for people with high self-esteem (high market value) to go out and acquire new friends to form more satisfying relationships with. Thus, the relationship between self-esteem and life satisfaction is weaker.

ECONOMIC ENVIRONMENTS

Economic Downturns

The economy is another sort of not-quite-physical environment that shapes human culture. For example, researchers in the 1940s analyzed data on cotton prices and lynchings of blacks in the U.S. South (Hovland & Sears, 1940). They found that when the cotton economy was bad, there were more lynchings. This suggests that racial attacks were at least partially motivated by economic frustration.

One historic study of how changes in the economic environment affect people was Glen Elder's (1999) *Children of the Great Depression*. Elder followed 167 children, born in 1920 and 1921, who grew up in what was probably the worst economic recession in U.S. history, then experienced the post-World War II economic boom. Elder followed these children over time and witnessed changes in their values toward material needs. He found that the economic deprivation in their formative years made them value material success in their early adulthood. The post-World War II economic boom and the GI Bill made many of the participants indeed far more materially successful than their parents.

Sales (1972) theorized that economic hard times make people more likely to join authoritarian religions. He built on laboratory findings that raising people's perception of threat increases their endorsement of authoritarianism. Based on this finding, he analyzed the number of conversions to more authoritarian churches (e.g., Roman Catholic, Southern Baptist) versus less authoritarian churches (e.g., Presbyterian) in the United States. He found that more people converted to authoritarian religions during economic downturns, whereas more people converted to less authoritarian religions during economic booms. There are, of course, other possible explanations as well. For example, Catholic and Southern Baptist churches may also be more communal, whereas mainline Protestant churches may be less communal and more prosperous (A. Cohen & Neuberg, [Chapter 32](#), this volume).

Modernization and Wealth

In addition to economic downturns, researchers have studied what happens when cultures become wealthier over time. Triandis (1989) theorized about how wealth affects people's view of the self. He argued that some cultures think more about the private self, the public self, or the collective self. He reviewed evidence that people in more developed cultures think more about the private self and the public self, but less about the collective self.

Baumeister (1987) made a similar argument: He studied historical documents and found that self-identity was rarely a problem in Western culture in the Middle Ages, but it became a problem in the modern era. Why were identity crises so rare in the Middle Ages? People often lived and died in the same village. Most people inherited their occupation and even their reputation from their family. That made it hard for people to be undecided about their identity—it was already decided for them. Yet as the economy grew more complex and people could choose between different careers, meet new people, and move away from home, people started worrying about how to decide what their identity should be, and identity crises became more common.

Greenfield (2004, 2009) studied modernization on a smaller scale with the Zinacantec Mayan people of Mexico. She studied the Zinacantec as their economy shifted from a subsistence agricultural economy to an economy of money and commerce. She found that the culture became more individualistic as it modernized.

One example was how parents taught their children. In the past, Zinacantec mothers taught their daughters how to weave clothes. But over time, the mothers were more often busy with work, such as selling goods in another city or making embroidery to order. In response, children became more independent and started learning on their own through trial and error.

Researchers have also studied how the shift to a market economy changed the culture of the Oksapmin people in New Guinea (Saxe, 1999). In the 1970s, the Oksapmin lived by hunting and farming. But soon a market economy developed, and many people started working in stores for wages. This shifted the culture toward commerce and money.

Saxe (1999) studied how this shift toward commerce affected cognitive style. For example, the Oksapmin traditionally thought of numbers very concretely. The word for *thumb of the right hand* was the same as the word for *one*. But as the culture embraced commerce, they developed a more

abstract system of numbers. This new system made it easier to add and subtract numbers, which was probably helpful for doing business, although it was less connected to concrete numbers like fingers on the hand.

China is another example of a society that modernized rapidly. Yan (2002) studied how love and marriage changed in a village in northern China as the country developed from 1950 to 2000. He studied records of marriages and found that people in the village traditionally married based on the advice of their parents. In 1950, 73% of marriages were arranged. Marriages affected the family's social standing, so they were often a pragmatic decision involving the whole family.

But as the economy developed, children began having more free choice in their marriages. In the 1990s, not a single marriage was arranged in the village. Young people started emphasizing romantic love over family considerations. Yan (2002) found that children often used the lyrics of pop songs to express their romantic love to each other, perhaps to avoid the embarrassment of expressing it directly. Marriage had shifted from a collective decision to a more personal decision.

Friendship is another type of relationship people have less choice over in less wealthy areas. In his time in West Africa, Adams (2005) noticed a cultural belief he rarely saw in the United States: enemyship. People in Ghana warned people to beware of enemies among their friends. One local bumper sticker read: "I am afraid of my friends, even you." Adams interviewed Ghanaian and U.S. participants about their views on friendship. The Ghanaian participants reported experiencing enemyship much more frequently than the U.S. participants.

Adams (2005) conjectured that economic hardship may make enemyship more likely. Economic hardship may put people in situations where they have to split resources, hide resources from their friends, and compete with them for scarce goods. At the same time, poverty may limit people's freedom of movement and their ability to extract themselves from unsatisfying relationships.

In contrast to these detailed studies of individual cultures, Inglehart (2000) has studied modernization from the perspective of the world at large (Inglehart, Foa, Peterson, & Welzel, 2008). Inglehart (2000) has analyzed global surveys that include cultures that represent 75% of the world's population. He found that people in less developed countries focus on

survival goals, such as developing the economy regardless of pollution or preserving traditional culture. Yet people in wealthier countries more often emphasize lifestyle goals, such as protecting the natural environment even at the cost of economic growth. This fits with Maslow's (1943) classic hierarchy of needs, which argues that people focus first on basic survival needs and only after these needs are met do they focus on higher-order needs such as self-actualization.

Socioeconomic Status

Researchers have also studied how different socioeconomic classes within the same nation might be different subcultures. In general, researchers have found that high-status cultures tend to emphasize free will and personal choice, whereas low-status cultures tend to emphasize fitting in and obligation (see Kraus, Callaghan, & Ondish, [Chapter 27](#), and Markus & Hamedani, [Chapter 1](#), this volume). In one study, researchers compared the lyrics from songs liked by college-educated Americans and high school-educated Americans (Snibbe & Markus, 2005; Stephens, Markus, & Townsend, 2007). They found that the songs liked by the college-educated Americans emphasized uniqueness and influencing other people. In contrast, the songs liked by high school-educated Americans emphasized maintaining integrity and adjusting the self.

The researchers also found that more educated Americans put more value on free choice (Snibbe & Markus, 2005, Study 3). In one condition, the researchers randomly assigned participants to choose one of four pens to use, then rate how much they like it. In another condition, participants chose a pen, but then the researcher told them that was the last pen of that kind, then gave them a different pen. More educated Americans rated the pen lower if it they had not chosen it. In contrast, the lack of choice did not change the ratings of the high school-educated participants.

This emphasis on free choice mirrors differences across nations. Americans are more likely to see actions (such as buying a TV or picking a topic for a class project) as choices, but people in India are less likely to see their behaviors as choices (Savani, Markus, Naidu, Kumar, & Berlia, 2010). For example, researchers asked people in India and the United States to list

the things they did yesterday that were choices and things that were nonchoices. Americans listed significantly more choices than the Indian participants. Results were similar when Americans and Indians had to code the behaviors of people in a video as choices or nonchoices (Savani et al., 2010, Study 3).

There is also evidence of socioeconomic status (SES) differences in accommodation to the needs of others. For example, one study found that working-class Americans scored better on reading other people's subtle emotional expressions than upper-class Americans (Kraus, Côté, & Keltner, 2010). Researchers even found that high-SES students occupied more space than low-SES students while studying and lounging in an amphitheater on campus (Hoffman & Trawalter, 2014).

Researchers have also tested for cognitive differences between SES groups. We know from prior research that people from individualistic cultures tend to think more analytically (Nisbett et al., 2001). If high-SES people are more individualistic, they probably also think more analytically. In contrast, low-SES people should be more likely to think holistically. A study in the United States and Russia revealed that low-SES groups in both countries thought more holistically than did high-SES groups (Grossman & Varnum, 2010). Other studies have replicated this finding (Talhelm et al., 2015). In sum, economic and social class differences seem to create different cultures, even within the same nation. Kraus and colleagues ([Chapter 27](#), this volume) discuss SES in more detail.

POLITICAL ENVIRONMENTS

The political environment is another ecology created by people. Researchers have tested how different political environments affect people's behavior. The most straightforward way to test this is to compare countries with different political systems, although that comes with lots of third-variable problems. One way to minimize third variables is to test what happens after the political system of a single country changes over time.

Inglehart and Baker (2000) took advantage of the collapse of the Soviet Union to see whether the political changes altered people's values. They found that a shared history of communism was more important than the

economic booms and busts that followed. They could test this because, after communism fell in the 1990s, some post-Soviet countries grew sharply economically, such as Hungary and Slovenia. Other post-Soviet countries fell into economic collapse, such as Russia, Estonia, and Latvia. Did this economic growth push Hungary and Slovenia toward secular values and Russia and Latvia away from secular values?

Under the Soviet Union, most of these nations strongly endorsed secular values and mostly did not support self-expression values. The economic booms and busts in the 1990s did not cause large changes in people's values. However, their shared history of communism seemed to have a lasting effect on their values.

Another effect of Communist systems is on women's place in society. Many people in the West think of the rise of communism as having negative effects on society. For example, some writers have looked at China's low trust in strangers and attributed it to the chaotic Cultural Revolution (Wielander, 2013).

But communism has had some effects that fit quite well into the value system of modern societies. For example, communist governments often encouraged women to enter the workforce. Chairman Mao famously said that women hold up half the sky. This ideology was not just empty words; it led to real changes. Even after the fall of Communism, former communist countries have higher rates of female labor force participation (Alesina et al., 2013).

Income Inequality

Income inequality is another important part of the political environment. Of course, income inequality is an economic phenomenon, but governments influence inequality through tax laws and social programs. Researchers have tested how inequality affects society by testing people in 15 countries with high and low income inequality (Loughnan et al., 2011). They asked students to rate themselves on positive values and personality traits, then rate the average student. People in countries with high income inequality rated themselves as much more positive than the average student—they self-enhanced a lot. In more equal countries such as Germany and Japan,

students rated themselves closer to the average student (although still a bit more positively than they rated others). Self-enhancement is often linked with individualism, but wealth inequality predicted self-enhancement better than countries' individualism scores (p. 1256).

Why would inequality make people more likely to self-enhance? Loughnan and colleagues (2011) argued this is because inequality makes people want to signal that they are a part of the “winning” part of society. But if people are more or less equal in a society, it is less necessary to try signal that you are in the successful tier of society.

Research also links income inequality to happiness. There is evidence that Americans are less happy when income inequality is high (Oishi, Kesebir, & Diener, 2011). Americans have reported their happiness since 1972 on the General Social Survey. Over that time, income inequality has gone up and down (most recently, up). During years with high inequality, Americans were less happy. This relationship was mediated by lower general trust and lower perceived fairness. People seem to be aware of this inequality, and they feel that society is less fair.

Is the effect of inequality limited to lower income brackets? To find out, the researchers analyzed the effect of income inequality across income brackets. Inequality had a strong effect among people in the lowest 20% of the income bracket ($r = -.54$, $p < .01$) and the 20–40% group ($r = -.63$, $p < .01$).

What about rich people? Rich people might be happier because inequality tends to be good for people on the top. The top 20% of the income bracket earned more money in unequal years. However, they were not any happier when inequality was high ($r = .03$, $p = .88$). Thus, it seems that no one is happier when income inequality increases—not even the people who are benefiting financially.

One way to reduce income inequality is progressive taxation. Progressive taxes charge wealthy people a higher percentage of their income than poor people. Countries that have more progressive tax rates (such as Sweden and Denmark) are happier than countries with less progressive tax rates (such as Hong Kong and Russia; Oishi, Schimmack, & Diener, 2012). This study did not have data on trust and perceived fairness, but it did have data on satisfaction with public goods, such as transportation and education. The data showed that the relationship between tax rates and happiness was

mediated by satisfaction with public goods, which can be paid for with progressive taxes. Countries with progressive taxes tend to have better public services, and these seem to increase people's well-being.

CHANGES WITHIN CULTURES OVER TIME

One important way to test theories of cultures is to study changes within a single culture over time. Like natural experiments (e.g., Uskul et al., 2008; Talhelm et al., 2014), studies within a single culture over time can help control for the effect of third variables that can confound comparisons of different cultures, such as language and religion.

Twenge (2001, 2006) has analyzed several longitudinal surveys to see how Americans have changed over the last century. One of the biggest changes is that Americans have become more likely to endorse individualistic values and the importance of the self. For example, in the 1950s, only 12% of Americans agreed with the statement "I am an important person." In the 1980s, 80% agreed (Twenge, Konrath, Foster, Campbell, & Bushman, 2008). Americans have also expressed individuality in another way: They are more and more likely to name their children with unique rather than popular baby names (Twenge, Abebe, & Campbell, 2010).

Why have Americans become more individualistic? Grossman and Varnum (2015) used time lag analysis to try to tease apart these changes over the last 100 years. They used markers of individualism from year to year, such as unique baby names, divorce rates, and the percentage of people living alone. They tested five potential causes of individualism: the shift to white-collar jobs, urbanization, declining religiosity, infectious disease, and disasters. They found that white-collar shifts were the only consistent predictor of increasing individualism. This fits with earlier research indicating that white-collar professions tend to emphasize individual initiative and autonomy, whereas blue-collar professions tend to emphasize following directions (Kohn & Schooler, 1973). As the United States became wealthier and more people moved into white-collar jobs, indicators of individualism increased.

Japan is another interesting test case of change within a culture over time. Japan's per-capita GDP rocketed from about US\$2,000 in 1950 to over

\$20,000 in the year 2000 (in constant 1990 dollars controlling for purchasing power; Maddison, 2003). In the 1950s, Japan had less than half the wealth per person compared to Western Europe. In the 1970s, Japan surpassed Western Europe. So did Japan become more individualistic as it became wealthier?

Hamamura (2012) tested this question by analyzing Japanese people's responses to large-scale surveys. Over several decades, some measures of individualistic values have risen, but many have gone in the opposite direction. For example, the percentage of people saying that it is important to "respect individual rights" has gone down over time. Meanwhile, the percentage of people agreeing that it is important to emphasize "social harmony" has gone up. At the very least, Japan has not become consistently more individualistic as it has become wealthier.

FUTURE DIRECTIONS

Understudied Regions

Ecological psychology has made lots of progress in the last 20 years, but there is much to be done. For one thing, large parts of the world have been studied very little. To demonstrate how research attention is distributed, we searched the PsycNet database (a.k.a. PsycINFO) for articles with the word *culture* and the names of the three most populous nations in East Asia, Africa, and South America. The nations in South America and Africa had less than 20% of articles that East Asia had ([Figure 4.7](#)). These understudied continents are ripe for research.

FIGURE 4.7. Number of articles containing the word *culture* and the name of the three most populous countries in East Asia, South America, and Africa. Search results are from PsycNET on September 23, 2015. Far less research is done on South American and African countries.

Microcultures

Researchers have argued many times that nations are not the best unit of analysis (Conway et al., 2014; Georgas & Berry, 1995). The problem is that cultures are not always perfectly contained within nations. For example, Catalonians in Spain argue that their culture is different from the rest of Spain. In the same way, Germany is now united, but researchers have found differences between the old East and West German regions (Frese, Kring, Soose, & Zempel, 1996).

Yet researchers in the past decade have added many studies on differences within nations (Greenfield, 2009; Grossman & Varnum, 2015; Kitayama et al., 2006; Talhelm et al., 2014; Uskul et al., 2008). Cultural psychology has become more balanced between the value of research between nations and within nations. At the same time, there is pragmatic value in using nations as the unit of analysis. Lots of data are available at the nation level but not at the regional level. And, of course, nations are

important units, too. We reject the idea that researchers should *never* study nations.

Although researchers have studied more regional cultures, one area that is largely unaddressed is what we might call “microcultures.” Microcultures can be cultures in different parts of a city, say, Manhattan and Brooklyn (Rentfrow & Jokela, [Chapter 29](#), this volume). Different companies may also have microcultures, and cultural psychologists have rarely turned their lens onto the cultures of companies. Even different divisions within organizations can have different cultures (such as the IT department and the sales department in a company or the humanities department and the engineering department in a university. Delving into these microcultures can help us get a better understanding of how culture works.

More Systematic Comparisons

Another path forward in ecological psychology is to test theories more systematically. For example, many studies are based on a sample of two countries or people within a single country. Yet, if a theory is true and general, it should hold across different samples, different nations, and different cultures. If studies replicate across different samples, the end result should be theories that are more robust. One example of this type of research is a study in which researchers tested people on common economic games in 15 small-scale societies (Henrich et al., 2005).

Another path is to create a more systematic look at ecological variables. Georgas and Berry (1995) grouped variables such as climate, education, and media to create a taxonomy of ecological variables (Georgas & Berry, 1995). They later refined the taxonomy and tested whether it could predict cultural values and happiness across cultures (Georgas, Van De Vijver, & Berry, 2004).

According to Georgas and Berry (1995), this approach could help refine the way cultural psychologists work. They argued that cultural psychologists often work by noticing a difference between cultures, testing it, then guessing at an explanation afterwards. Instead, researchers should at least sometimes start with a set of ecological variables and make predictions in a deductive way (Georgas & Berry, 1995, p. 127).

Underused Methods

Finally, one way to expand ecological psychology is to use more diverse methods. We can gain new insight by conducting longitudinal analyses (e.g., Hamamura, 2012), field experiments (Johansson, Hartig, & Staats, 2011), and laboratory experiments (Oishi et al., 2007). These methods usually require more time and effort, but they offer valuable evidence.

New types of data analysis can also push the field forward. One rich source of new methods is economics. Because economists often analyze nonexperimental data, they have developed more techniques that look for clues of causality in nonexperimental data. Psychologists can pick up new tools such as the following:

- *Instrumental variable regression* tries to get around reverse causality by replacing the variable that might have been chosen by humans (such as choosing to farm rice) with a variable that is not plausibly caused by humans (the proper soil and rainfall for rice; Alesina et al., 2013; Talhelm et al., 2014). The section “[Reverse Causality](#)” in this chapter describes two examples of instrumental variables (but see Cohen, [Chapter 6](#), this volume, for some cautionary examples).

- *Regression discontinuity* looks for a discrete change at a single point in time or physical space. For example, the Spanish colonial government assigned certain districts in Peru to forced labor in silver mines (Dell, 2010). Yet people right across the border of these districts were exempt. That created a situation in which one variable (forced labor) changed sharply at the district border, whereas other third variables (such as elevation and ethnicity) did not. Dell found that these historical borders of forced labor predicted worse economic and health conditions in modern-day Peru.

- *Phylogenetic analysis* builds trees of cultural descent to test whether two variables are related through common ancestry rather than causality. This is perhaps easiest to understand with the example of dairying and lactose tolerance (Holden & Mace, 2009). One plausible hypothesis is that after a group of people started keeping animals for their milk, they became more likely to develop the ability to easily break down the lactose in milk into adulthood. A simple analysis would take a sample of nations and correlate (1) whether that nation practiced dairying and (2) the percentage

of people who are lactose tolerant in that nation. One problem with this analysis is that it would treat all of northern Europe as independent cases. Lactose tolerance is high in Ireland, the United Kingdom, the Netherlands, and so on. Yet these cultures also share common ancestors. So are the Irish lactose tolerant because they practiced dairying or because they descended from people who were lactose tolerant? Phylogenetic analysis corrects for this by taking into account common ancestry and estimates of when cultures adopted a practice (see also Mesoudi, [Chapter 5](#), this volume).

Students of culture will always struggle with the question of causality, but these new methods can get us closer to that goal.

CONCLUSION

We think the wealth of research we cite in this chapter shows that ecological psychology has grown from a minor thread in the field to a burgeoning field. This happened as cultural psychology pushed from documenting cultural differences to searching for the causes of those differences. Of course, ecological research on culture is not solely the domain of psychology. Ecological research stretches from anthropology, which has long been concerned with culture, to economics, in which the study of culture has only more recently become accepted (e.g., Alesina et al., 2013).

We sometimes refer to this field as “socioecological psychology” to remind ourselves not to be too literal about what counts as an environment. Temperature, rainfall, and natural disasters are classic features of the environment. Yet the environment is also human. We have to navigate human environments such as democracies versus autocracies, wide open spaces versus densely populated spaces, and relationally mobile versus stable communities. Human environments are environments, too.

As the field moves forward, we see exciting areas of opportunities. Vast parts of the world have received very little research, such as Africa and South America. There are techniques developed in biology and economics that can help us tease apart the age-old question of cause and effect—a question that nips at studies of culture in particular, because true

experiments are often impossible. Researchers who push forward in these paths will likely lead the field forward.

Finally, we think ecological thinking can be a source of inspiration for researchers, even for researchers not “officially” interested in culture. Social psychologists have long debated whether we should study human behavior as driven by stable individual differences or as driven by situations (Mischel, 1968). Ecological psychology can offer inspiration for researchers to think of how human behavior is shaped by—or is suited to navigate—environments defined more broadly.

CHAPTER 5

Cultural Evolution and Cultural Psychology

Alex Mesoudi

Cultural evolution, a branch of the evolutionary sciences, assumes that (1) human cognition and behavior are shaped by both genetic and cultural inheritance, and (2) cultural inheritance constitutes a Darwinian evolutionary system that can be analyzed and studied using tools borrowed from evolutionary biology. In this chapter, I explore the many links between the fields of cultural evolution and cultural psychology. First, understanding the evolutionary context within which human psychology emerged gives added significance to the findings of cultural psychologists, reinforcing cultural evolutionists' claims that humans inhabit a "cultural niche" where the major means of adaptation to different environments is cultural rather than genetic. Second, a focus on cultural transmission pathways, drawing on cultural evolution models and findings, can explain the maintenance of, and changes in, cultural variation in psychological processes. Third, cultural evolutionary methods offer powerful means of testing historical ("macroevolutionary") hypotheses put forward by cultural psychologists for the origin of psychological differences. Finally, cultural psychology can play a central role in a synthetic evolutionary science of culture, providing valuable links between individual-oriented disciplines, such as experimental psychology and neuroscience, and society-oriented disciplines, such as anthropology, history, and sociology, all within an evolutionary framework rooted in the biological sciences.

In the last few decades, cultural psychologists have demonstrated that it is a mistake to assume that people everywhere think the same way (Heine, 2011; Kitayama & Uskul, 2011). Research has demonstrated significant and systematic cultural variation in people's self-concepts (Markus & Kitayama,

1991; Markus & Hamedani, [Chapter 1](#), this volume), social orientation (Oyserman, Coon, & Kemmelmeier, 2002; Triandis & Gelfand, 1998), cognitive reasoning (Nisbett, Peng, Choi, & Norenzayan, 2001; Nisbett, [Chapter 7](#), this volume), perception and attention (Kitayama, Duffy, Kawamura, & Larsen, 2003; Masuda, Russell, Li, & Lee, [Chapter 8](#), this volume; Nisbett & Masuda, 2003), aggression (Nisbett & Cohen, 1996), cooperation (Henrich et al., 2005), personality (Heine & Buchtel, 2009; McCrae, Yik, Trapnell, Bond, & Paulhus, 1998; Rentfrow & Jokela, [Chapter 29](#), this volume), and moral reasoning (Haidt, Koller, & Dias, 1993; Miller, Wice, & Goyal, [Chapter 16](#), this volume), among many other domains. Phenomena once considered to be fundamental, universal aspects of human psychology, such as the so-called “fundamental attribution error” (Ross, 1977) or linear stages of moral reasoning (Kohlberg, 1969), have been shown to be far from universal (Haidt et al., 1993; Heine & Hamamura, 2007). As expressed in one memorable review, psychologists’ overreliance on studies of people from WEIRD (Western, Educated, Industrialized, Rich, Democratic) societies to draw conclusions about a single “human” psychology is hugely problematic, as such people are far from representative of our species as a whole (Henrich, Heine, & Norenzayan, 2010).

Interestingly, just as psychologists are beginning to appreciate the role that culture plays in shaping cognition and behavior, so too are evolutionary scientists. The field of cultural evolution (encompassing gene–culture coevolution, sometimes called “dual-inheritance theory”) is based on the premises that (1) human cognition and behavior are shaped by not only genetic inheritance but also cultural inheritance (a.k.a. social learning), and (2) this cultural inheritance constitutes a Darwinian evolutionary system that can be analyzed and studied using tools borrowed from evolutionary biology (Henrich, 2015; Mesoudi, 2011, 2016a, 2016b; Richerson & Boyd, 2005; Richerson & Christiansen, 2013). “Culture” here is defined in a broad way to encompass all of the knowledge, beliefs, values, attitudes, and so forth, that we acquire from others via social learning/cultural transmission (e.g., via imitation or spoken/written language).

My aim in this chapter is to illustrate the numerous conceptual and methodological compatibilities between the fields of cultural psychology and cultural evolution, and the mutual benefits that can be gleaned through their further integration (see Mesoudi, 2009a, for a similar argument for

social psychology). Essentially, evolutionary theory and methods provide answers to “why” questions. In biology, this might concern why particular biological adaptations (e.g., eyes or wings) exist, why species are distributed geographically the way that they are, and why and how populations change genetically over time. For culture, including culturally influenced psychological processes, cultural evolutionary theory and methods can answer equivalent questions: why culturally variable psychological processes or dimensions exist in the first place; why psychological processes are distributed geographically the way that they are; and why and how they change culturally over time. Cultural evolutionary theory provides rigorous, quantitative methods for answering such questions that have proven hugely successful in the biological sciences. Although cultural psychology has its roots in more humanities-based cultural anthropology traditions such as semiotics (Shweder & Sullivan, 1993), aligning the field with the evolutionary/biological sciences promises to open new opportunities, introduce powerful new methods, and add new significance to cultural psychologists’ important findings.

I explain in the following section the basic tenets of cultural evolutionary theory and explore in a subsequent section a fundamental but often taken-for-granted question: Why should psychological processes be culturally variable at all? I then discuss how the maintenance of cultural variation in psychological processes might be explained in terms of cultural transmission pathways, before discussing how cultural evolutionary methods can shed light on the historical origin of that variation. I conclude by noting that cultural psychology can play a crucial role in a synthetic evolutionary science of culture.

WHAT IS CULTURAL EVOLUTION?

The earliest attempt to apply evolutionary theory to human behavior and cognition, *sociobiology* (Wilson, 1975), tended to treat culture as a proximate means by which genes act to maximize inclusive genetic fitness (see Laland & Brown, 2011, for a detailed history of the human evolutionary behavioral sciences). The focus of sociobiology was on human universals that were assumed to reflect the genetic unity of the human species or, at most,

genetically determined responses to environmental regularities. This continued within prominent strands of *evolutionary psychology*, such as Tooby and Cosmides's (1992) emphasis on universal psychological mechanisms (Brown, 1991; Tooby & Cosmides, 1992, p. 45) and on "evoked" rather than transmitted culture (Gangestad, Haselton, & Buss, 2006; Tooby & Cosmides, 1992, p. 116), in which universal genetic programs are triggered by particular environmental conditions. This focus on universality and genetic inheritance left little room for exploring or explaining cross-cultural variation (but see Apicella & Barrett, 2016).

Parallel to this, there developed a strand of evolutionary research that aimed to incorporate culture more comprehensively into evolutionary models of human behavior, known as *cultural evolution* (incorporating gene-culture coevolution, sometimes called dual-inheritance theory; Boyd & Richerson, 1985; Cavalli-Sforza & Feldman, 1981; Lumsden & Wilson, 1981). While the first formal, quantitative models of cultural evolution appeared in the 1970s and 1980s, it is interesting to note that this movement took much inspiration from the earlier writings of Donald Campbell (1960, 1965, 1975). This is noteworthy because Campbell also conducted pioneering early work in cross-cultural psychology (e.g., Segall, Campbell, & Herskovits, 1963), perhaps attesting to the compatibility of the two fields even at that early stage. Cultural evolution theory is based on the premise that cultural change constitutes a Darwinian evolutionary process that acts in parallel to, and interacts ("coevolves") with, genetic evolution. Human cognition and behavior are therefore constituted by these twin tracks of genetic and cultural inheritance: Sometimes the latter may reinforce the former (i.e., culture is genetically adaptive), whereas at other times cultural evolution may result in biologically maladaptive or neutral behavior due to its partial independence.

What is meant when we say that culture is a "Darwinian evolutionary process"? Although many textbook definitions of "evolution" mention genetic inheritance or the natural selection of genetic variation, Darwin's conceptualization of evolution in *The Origin of Species* (1859/1968) was actually quite mechanism-neutral given that little was known at that time about genes or genetic inheritance. In general terms, Darwinian evolution comprises three principles (Lewontin, 1970): (1) variation, such that entities vary in their characteristics; (2) differential fitness, such that some entities

are more likely to persist than others, and this likelihood is determined to some extent by their characteristics; and (3) inheritance, such that entities pass on their characteristics to subsequent entities. Over time, those characteristics that make their bearers more likely to persist tend to increase in frequency.

Applied to species, these general principles have been observed in action many times in wild populations. One classic example involves Darwin's finches on the Galapagos Islands (Grant, 1986). During one 3-year period in the 1970s, it was shown that (1) finches' beak sizes varied (variation); (2) during a drought, finches with larger beaks were able to open more varied seeds and so were more likely to survive and reproduce (differential fitness); and (3) beak size is passed from parents to offspring (inheritance). Over time, beak size increased in the population. Many such cases of evolution in action have been documented since Darwin's original formulation.

The same principles apply to cultural change (Mesoudi, Whiten, & Laland, 2004). Cultural traits (beliefs, attitudes, skills, values, etc.) vary within a population; some traits are more likely to persist than others (e.g., some ideas are more memorable, some attitudes fit with preexisting attitudes, some skills are more effective), and traits are passed on to other individuals via social learning (imitation, teaching, spoken/written language, etc.). Thus, culture evolves. Importantly, the argument is not that cultural evolution is necessarily identical to genetic evolution in any further details (Mesoudi, 2011). In many respects it appears not to be, and exploring the specific dynamics of cultural evolution is a prime activity of cultural evolution researchers. For example, while genetic mutation is largely blind with respect to selection, cultural "mutation" (or "innovation") may well be consciously guided or directed by intentional human agents (Mesoudi, 2008). While genetic variation comes in discrete units (genes), there is no requirement for cultural variation to come in discrete units (while such "memes" may exist in certain domains, they are not necessary for evolution to occur; Henrich, Boyd, & Richerson, 2008). While genetic inheritance usually follows strict Mendelian laws, such as requiring that individuals receive half of their genes from each parent (in sexually reproducing organisms, at least), cultural traits may be acquired from any number of genetically unrelated individuals and follow nonrandom social learning biases, such as conformity (see below). Also, while genetic inheritance

generally does not itself typically generate evolutionary change, social learning may do so, as traits are transformed during transmission (Acerbi & Mesoudi, 2015).

Recognizing these differences, cultural evolution researchers have sought to mathematically model, experimentally simulate, and document “in the wild” how cultural evolution operates within populations of individuals: where cultural variation comes from, how it changes over time, and how it is transmitted from individual to individual (Cavalli-Sforza & Feldman, 1981; Mesoudi, 2011, 2016a, 2016b; Rendell et al., 2011; Richerson & Boyd, 2005; Richerson & Christiansen, 2013). These are the details of cultural “microevolution” (see [Figure 5.1](#)). Researchers have examined when and why people copy their parents, as opposed to nonparents (Cavalli-Sforza & Feldman, 1981; McElreath & Strimling, 2008). There are many ways to learn from nonparents, and there has been much research into “social learning strategies” or “biases” (Laland, 2004; Rendell et al., 2011) that describe how people learn and from whom, such as “conformity,” defined as disproportionately copying the most common trait in one’s group (Henrich & Boyd, 1998; Morgan & Laland, 2012); “prestige bias,” defined as preferentially copying high-status individuals (Cheng, Tracy, Foulsham, Kingstone, & Henrich, 2013; Henrich & Gil-White, 2001); and “content biases,” in which particular ideas are preferentially transmitted, such as those that invoke disgust (Eriksson & Coultas, 2014; Heath, Bell, & Sternberg, 2001) or concern social interactions (Mesoudi, Whiten, & Dunbar, 2006; Stubbersfield, Tehrani, & Flynn, 2014).

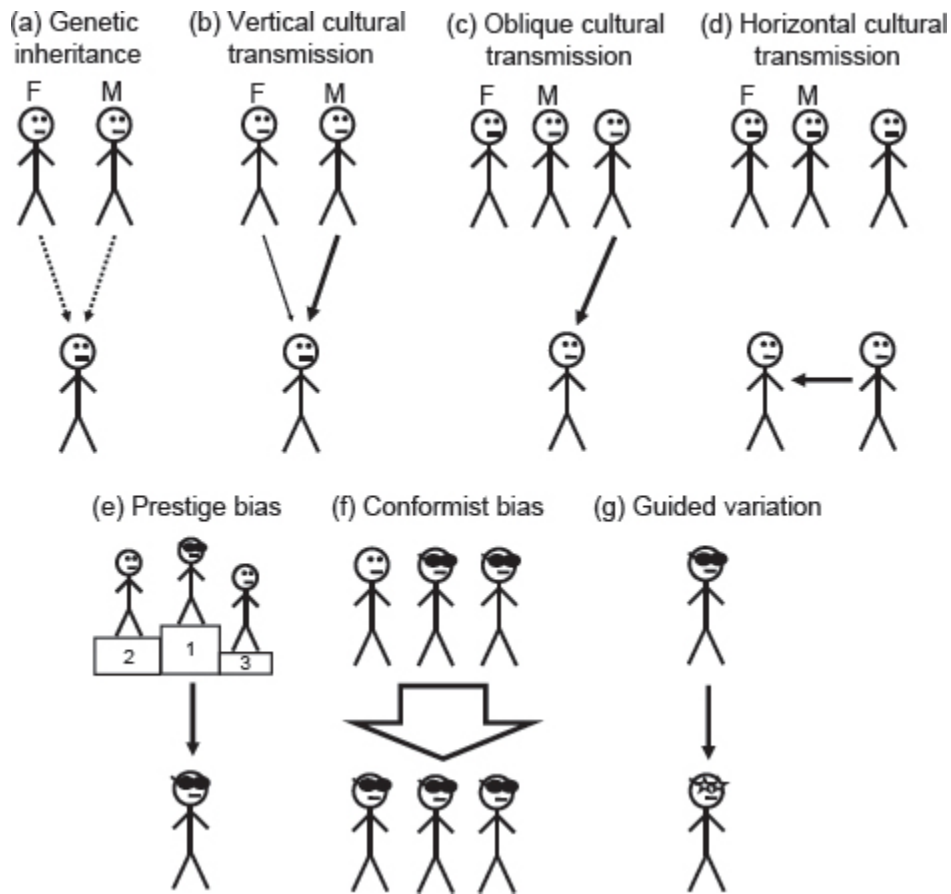

FIGURE 5.1. Commonly studied processes of cultural microevolution. Compared to (a) genetic inheritance, in which information is inherited from a father (F) and mother (M), cultural transmission can take many pathways: (b) vertical cultural transmission entails copying biological parents, although one parent might be more influential than the other (here, the mother is more important, as has been shown for traits such as religion [Cavalli-Sforza, Feldman, Chen, & Dornbusch, 1982]; in other cases, the father may be more important); (c) oblique cultural transmission entails copying a nonparent from the parental generation (e.g., a teacher or elder); (d) horizontal cultural transmission occurs within generations, between peers. Oblique and horizontal cultural transmission may be biased in different ways: (e) prestige bias involves copying the trait (here, wearing sunglasses) of a successful or high-status individual; (f) conformist bias involves disproportionately copying the most popular trait in a group (here, sunglasses are worn by a majority of the demonstrators, so they are adopted by all learners in the next generation); and (g) guided variation occurs when individuals transform traits in a non-selection-like manner.

As well as these transmission biases, there has been much recent attention on migration, population size, and other demographic factors that foment cultural change and structure cultural variation (Derex, Beugin, Godelle, & Raymond, 2013; Henrich, 2004; Kempe & Mesoudi, 2014; Powell, Shennan, & Thomas, 2009). Small populations, for example, reduce

the available number of skilled demonstrators, potentially resulting in the loss of cultural complexity. This purportedly occurred when Tasmania became cut off from the Tasmanian mainland about 10,000 years ago (Henrich, 2004). Conversely, the *emergence* of cultural complexity in Europe about 45,000 years ago, in the form of multipart technological artifacts such as bows or spearthrowers, has been attributed to *increases* in population density, as larger or more interconnected populations can prevent the accidental loss of complex traits (Powell et al., 2009).

Cultural macroevolution involves large-scale cultural change over long time periods and the emergence of cultural variation over large geographical areas. Biologists often study biological macroevolution using *phylogenetic* methods, which use the current distribution of species to infer the likely evolutionary history of those species. These histories are often tree-like given the assumption of high-fidelity genetic inheritance that generates lineages of similar individuals. Cultural evolution researchers have used the same methods to reconstruct the evolutionary history of certain cultural traits that have similarly strong descent through high-fidelity cultural transmission, such as languages (Bouckaert et al., 2012; Pagel, 2009), folktales (Tehrani, 2013), prehistoric tools (O'Brien et al., 2014) and sociopolitical systems (Currie, Greenhill, Gray, Hasegawa, & Mace, 2010). Bouckaert et al. (2012), for example, used phylogenetic analyses to show that the Indo-European language family most likely originated around 8,000–9,500 years ago and spread with agriculture, rather than a more recent origin in the Pontic steppes. While cultural macroevolution may proceed at a purely descriptive level to reconstruct historical patterns of cultural change, it is also possible to explain the emergence of such patterns via links to the aforementioned cultural microevolutionary biases. For example, Pagel, Atkinson, and Meade (2007) showed that more frequently used words are more likely to be preserved within language phylogenies, potentially due to a conformity-style process.

While these examples concern purely cultural evolution, gene–culture coevolution analyses that examine the coevolution of genes and culture often find that cultural evolution can significantly alter the course of genetic evolution (Durham, 1991; Laland, Odling-Smee, & Myles, 2010). Examples include the spread of lactose tolerance genes in societies that historically have exhibited the cultural practice of dairy farming, due to the nutritional

benefits of being able to digest milk in adulthood (Itan, Powell, Beaumont, Burger, & Thomas, 2009); the spread of sickle-cell anemia genes in regions of Africa with a cultural history of slash-and-burn agriculture, because such practices create standing water within which mosquitos breed, thus spreading malaria to which the sickle cell provides some resistance (Wiesenfeld, 1967); and the spread of alcohol dehydrogenase genes in Chinese populations with a history of rice farming, because such genes increase the amount of fermented rice products that can be consumed (Peng et al., 2010).

It is important to note that there is no assumption within modern cultural evolution theory that societies must progress along fixed stages of increasing “complexity.” This common assumption of 19th-century sociocultural “evolutionary” schemes (e.g., Tylor, 1871) stemmed from a misunderstanding of evolutionary theory. Neither biological nor cultural evolution entails inevitable progress along fixed, predetermined stages of increasing complexity, because no such stages exist; there is no sense in which one society is “more evolved” than another society, just as one species cannot be “more evolved” than another species (Freeman, 1974; Mesoudi, 2011). The aforementioned loss of complex cultural traits on Tasmania due to reduced population sizes provides a good illustration of the possibility of the loss, rather than inevitable increase, in complexity. There is also no requirement within modern cultural evolution theory to focus on any single level of cultural organization: Some studies focus on individual cultural traits (e.g., artifacts such as handaxes or arrowheads; Mesoudi & O’Brien, 2008; O’Brien et al., 2014); others focus on entire sociopolitical systems or nations (Currie et al., 2010; Pagel & Mace, 2004), depending on the research question of interest. Multilevel models can incorporate multiple levels of analysis, simultaneously tracking changes in, and interactions between, individual traits (e.g., prosociality) and larger societal organization (e.g., empires or religions; Norenzayan, 2013; Turchin, Currie, Turner, & Gavrilets, 2013).

THE EVOLUTION OF CULTURE: WHY HAVE CULTURAL PSYCHOLOGIES AT ALL?

Before getting to cultural dynamics themselves, it is useful to consider a more basic question: Why did a capacity for culture, and particularly cultural evolution, evolve in the first place? This deceptively simple question has received much attention in the cultural evolution literature. Many species get by with just genetic evolution, with some individual learning (e.g., classical or instrumental conditioning) to respond to environmental uncertainties that arise after birth. So why bother biologically evolving large, expensive brains that have a capacity for culture? This is not just a tangential issue: Knowing the likely evolutionary function of a trait can help one understand its current operation. And by considering this question, cultural psychology can forge links to other disciplines such as comparative psychology, behavioral biology, and biological anthropology.

One way of finding out about the evolutionary origin of culture is by looking for it in other species. This raises the immediate problem of how to define “culture.” History has shown that it is not particularly fruitful to spend too long arguing over definitions, and whether different species do or do not have culture: This typically results in territorial arguments between researchers over whether their favorite species can be placed in the “culture” club (Laland & Hoppitt, 2003). Comparative researchers have instead found it more scientifically productive to start with a broad definition and explore the different elements of culture found across different species.

Many species exhibit some form of “social learning”—defined as learning from conspecifics—which can be considered the basic foundation of culture (Laland & Galef, 2009). Bees learn the direction and distance to food via intricate waggle dances (Leadbeater & Chittka, 2007); many fish species learn routes to food or nesting sites by following others in shoals (Laland, Atton, & Webster, 2011); juvenile male songbirds of several avian species learn songs by listening to their fathers (Catchpole & Slater, 1995); whales learn from one another hunting techniques such as using bubbles to trap prey (Whitehead & Rendell, 2014); and nonhuman primates learn tool-use behaviors such as nut cracking from others (Whiten, Horner, & Marshall-Pescini, 2003). In some species, social learning is of sufficiently high fidelity that it may generate between-population differences in behavior, often called “cultural traditions” (Fragaszy & Perry, 2003). Examples include song dialects of birds and whales, or tool-use traditions in different groups of chimpanzees (Whiten et al., 1999). Some chimpanzee

groups crack nuts, others do not, and this population-level difference seems to occur because individuals in nut-cracking groups learn nut-cracking from one another, rather than any genetic differences or environmental factors that might encourage individual learning of nut cracking in one group rather than the other, such as the availability of nuts (Whiten, Horner, & de Waal, 2005).

These findings show that culture—in the sense of learning from others and generating group differences in behavior—is far from unique to humans, and indeed may be found in species such as fish or insects that have historically been dismissed as behaviorally “simple” or “primitive.” The widespread existence of social learning across animal species is consistent with findings from theoretical evolutionary models, which show that social learning can readily evolve when (1) environments change fast enough such that genes cannot predict what behavior will be adaptive during an organism’s lifetime (otherwise, genetic adaptation is sufficient), but not so fast that other individuals’ solutions to problems become outdated (otherwise, individual/asocial learning is more effective) (Aoki & Feldman, 2014; Aoki, Wakano, & Feldman, 2005) and (2) when individual learning is costly or difficult (Boyd & Richerson, 1985). Other models suggest that social learning is most effective when it is combined with individual learning (Boyd & Richerson, 1995; Enquist, Eriksson, & Ghirlanda, 2007), and when it follows certain nonrandom rules, such as a preferential tendency to learn from certain individuals (e.g., successful, older, or prestigious individuals) or to copy the group majority (conformity), as noted earlier (Laland, 2004; Rendell et al., 2011). Indeed, these social learning strategies are found in many nonhuman species: Fish preferentially copy the food source used by more successful group members (Kendal, Rendell, Pike, & Laland, 2009) while great tits conform to the majority foraging behavior in the group (Aplin et al., 2015).

Many cultural psychologists would probably argue that we are still missing some fundamental qualities of human culture in these descriptions of nonhuman culture. Indeed, there have been suggestions that much nonhuman social learning is underpinned by the same psychological mechanisms as associative (asocial) learning, just with other individuals as stimuli (Heyes, 2012; Leadbeater, 2015). Humans, on the other hand, seem to possess specific cognitive adaptations that allow the high-fidelity

transmission of information, which uniquely allow us to possess *cumulative* culture, in the sense that we learn from others that which we could never have invented alone (Dean, Vale, Laland, Flynn, & Kendal, 2014; Tomasello, 1999). Think of computers, cars, quantum physics, or financial markets: Such phenomena are the product of countless previous generations' modifications and innovations. Even the most sophisticated nonhuman cultural behaviors, such as chimpanzee nut cracking, could plausibly have been invented by a single chimpanzee alone (Tennie, Call, & Tomasello, 2009).

Recent experimental evidence comparing humans with nonhuman primates points to a set of cognitive abilities that uniquely support this cumulative culture, including teaching, language, and imitation (Dean, Kendal, Schapiro, Thierry, & Laland, 2012). One key capacity is "overimitation," the tendency of children (Lyons, Young, & Keil, 2007) and young adults (Flynn & Smith, 2012) to copy behaviors performed by others even when those actions have no immediate payoff or utility, such as tapping on the top of a puzzle box with a wand before using the wand to open the box and obtain food. Chimpanzees, by contrast, fail to overimitate, readily ignoring irrelevant actions (Horner & Whiten, 2005). While overimitation leads to the copying of irrelevant actions in the lab when devious developmental psychologists are involved, in the real world it probably makes evolutionary sense for children and young adults to slavishly copy whatever an older adult is doing, even when there is no immediate payoff. Manufacturing a stone handaxe, for example, requires a long sequence of actions before the handaxe is ready to be used, each of which has no clear immediate utility. Humans also display powerful norm-following behaviors in tasks with no material payoff at all (i.e., we follow behavioral rules demonstrated by others seemingly without any need for reinforcement or reward; Chudek & Henrich, 2011; Rakoczy, Warneken, & Tomasello, 2008). In one study, 2- and 3-year-olds shown how to play a novel, rule-based game later corrected a puppet that was playing the game "wrongly," often using normative language when doing so (e.g., "That's not how it's done") (Rakoczy et al., 2008). Again, this might seem trivial in the lab, but in the real world, norm-following behavior is the only way to acquire opaque social customs that, at least at first, make no intuitive sense.

Abilities such as overimitation and norm following allow the high-fidelity transmission of information and, indeed, accumulation of beneficial ideas, skills, and institutions over successive generations. According to this perspective, we inhabit a “cultural niche” in which the major means of adaptation to novel environments is not genetic or via individual learning, as in other species, but primarily via cumulative cultural evolution (Boyd, Richerson, & Henrich, 2011). Within this context, it is not so surprising to find cultural variation in human psychological processes. Humans, compared to other species, are cultural sponges, possessing cognitive adaptations for acquiring knowledge and behavior from others, even with no reward or reinforcement, and in an open-ended manner that is not restricted to a single learning domain (e.g., vocalization or food location). This flexibility and spontaneity seems absent in other species, despite their frequent use of social information in foraging, vocal communication, and other specific contexts.

When considering cultural-psychological patterns, then, it is useful to keep these broader evolutionary considerations in mind. Cultural adaptation can, and indeed should, occur at local levels in particular societies in response to particular selection pressures—there is no reason to assume or expect a universal human psychology, which we might expect under genetic adaptation. Most of the time, these cultural responses will be biologically adaptive for the individuals who possess them given that culture itself is a biologically evolved trait that, on average, increases fitness. But evolutionary models also show that this does not always lead to biologically adaptive behavior in practice. The very reason for culture’s existence is to track environmental change that is too fast for genes to track, and to acquire from others information that cannot be stored in DNA. We should therefore expect some degree of decoupling between cultural and genetic inheritance, such that genetically maladaptive behaviors may arise via cultural evolution. This might occur, for example, in phenomena such as copycat suicide (Mesoudi, 2009b), in which our tendency to copy others, particularly prestigious others, can lead to the spread of behaviors that are biologically maladaptive.

CULTURAL TRANSMISSION PATHWAYS: PROXIMATE EXPLANATIONS FOR THE MAINTENANCE OF CULTURAL VARIATION

Cultural psychologists have documented much variation across societies in various psychological processes. But how is this variation maintained over time, especially in the face of frequent migration? And in cases where cultural *change* has been documented over time, such as the increasing individualism in the United States and Japan (Hamamura, 2012; Twenge, Campbell, & Gentile, 2012), what causes this change in some traits but not others?

At a proximate level, such questions may be addressed in terms of transmission pathways: How are psychological characteristics transmitted from one person to another? And how do these individual-level dynamics link to population-level patterns of stability and change? Cultural evolution researchers have modeled the population-level consequences of “vertical cultural transmission” (i.e., learning from one’s biological parents), “oblique cultural transmission” (i.e., learning from unrelated elders), and “horizontal cultural transmission” (i.e., learning from same-generation peers) (Cavalli-Sforza, Feldman, Chen, & Dornbusch, 1982; Cavalli-Sforza & Feldman, 1981; McElreath & Strimling, 2008; see [Figure 5.1a–d](#)). These models suggest that vertical transmission causes slower cultural change than oblique transmission, because the former severely limits the number of people from whom one can learn (one or two), and cultural traits must spread within family units rather than across entire societies. Oblique transmission is in turn slower than horizontal transmission given that the former occurs over successive biological generations, while the latter occurs within generational time frames. Ethnographic studies inspired by these theoretical models have shown that parents are often stated as a source of knowledge using self-report methods (Hewlett & Cavalli-Sforza, 1986). However, studies that sidestep the problems of self-report (Nisbett & Wilson, 1977) and instead infer transmission from patterns of shared knowledge show that oblique and horizontal transmissions from more knowledgeable elders and peers are often more important overall, and particularly during late childhood, adolescence, and early adulthood, following brief vertical cultural transmission during

early childhood (Aunger, 2000; Demps, Zorondo-Rodríguez, García, & Reyes-García, 2012; Harris, 1995; Hewlett, Fouts, Boyette, & Hewlett, 2011; Reyes-García et al., 2009). This combination of vertical then oblique/horizontal makes adaptive sense: Initially copying one's parents provides an initial guess at the appropriate knowledge for one's environment, but this must then be updated by knowledge from others because one's parents are a small sample of just $n = 2$, who may not possess the full range of knowledge required to participate fully in society, and may possess out-of-date information.

Another possibility, of course, is that putative "cultural" variation in psychological processing is actually genetic, or at least genetically influenced. Few, if any, researchers would argue for a direct genetic explanation (e.g., that there are genes "for" collectivism, and that those genes occur with higher frequency in more collectivistic societies). However, there has been increasing interest in gene–culture interactions, with certain genes determining people's susceptibility to cultural inputs (Kim & Sasaki, 2014). This may provide an indirect explanation for between-population differences. For example, Chiao and Blizinsky (2010) argued that collectivism arose in East Asia as a cultural response to a higher frequency in those populations of an allele of a serotonin transporter gene, which is linked to a greater risk of mood and depressive disorders. The social support provided by collectivism provided a cultural "buffer" against these genetically influenced disorders.

One "seminatural" experiment that can shed light on these transmission pathways is migration ("seminatural" in the sense that migrants are not an entirely random sample of the original population, yet they are also not participating in a psychological experiment). Imagine a migrant who moves from one country (e.g., Korea or Japan) to another (e.g., the United States or Canada) in which the mainstream population typically has different psychological processes than the country of origin. The extent to which this migrant, and subsequent generations (e.g., the migrant's children) shift from the psychological processes typical of the country of origin to those typical of the mainstream adopted country may indicate how the between-society cultural variation is maintained. If migrants fail to shift to the local psychological processes even after several generations, this provides support for a direct genetic explanation or for exclusively vertical cultural

transmission, or oblique/horizontal cultural transmission solely within the migrant community. At the other extreme, if first-generation migrants shift immediately or soon after migration, this suggests powerful horizontal cultural transmission, perhaps via cultural interactions or cultural products within the new environment (Morling & Lamoreaux, 2008). If first-generation migrants retain the psychological processes of their heritage society, and a shift is observed in the second and subsequent generations born and raised in the adopted society, this indicates some mix of vertical, oblique, and horizontal transmission, with the speed of acculturation indicating the precise mix.

Several cross-cultural studies that have included Asian Americans alongside North American and East Asian nonmigrants have found that Asian Americans are typically intermediate between their East Asian parents and local North American psychological characteristics on measures such as self-enhancement (Heine & Hamamura, 2007) and reasoning style (Norenzayan, Smith, Kim, & Nisbett, 2002). This partial shift makes it less likely that genetic or exclusively vertical cultural transmission can explain broader between-population differences (which would predict no shift), and less likely that an explanation would be based exclusively on horizontal cultural transmission (which would predict an immediate and complete shift). It points instead to a mix of horizontal/oblique and vertical cultural transmission (with “oblique” in this case indicating transmission from older members of the adopted society, such as schoolteachers, rather than older members of the heritage society who may have migrated, too, although both are possible: I call these “local-oblique” and “heritage-oblique”).

In a recent study from my lab (Mesoudi, Magid, & Hussain, 2016b), we sought to add to this evidence base and, in addition, specifically address the issue of cultural transmission pathways derived from the cultural evolution literature by also measuring potential markers of local-oblique and horizontal cultural transmission (e.g., local education and mass media exposure) and heritage-oblique and vertical cultural transmission (e.g., time spent with one’s family). We applied a battery of psychological measures previously shown to vary cross-culturally to first- and second-generation British Bangladeshi migrants living in East London, along with nonmigrants from East London. Measures included individualism and collectivism, dispositional and situational attribution (both of these were measured as

separate constructs rather than two ends of a continuum given previous research suggesting that they are independent dimensions (e.g., Oyserman et al., 2002), social closeness, categorization, self-enhancement, and drawing style. While some measures showed no variation between the cultural groups, several showed the expected partial shift found in the aforementioned studies of East-to-West migrants. For example, first-generation migrants exhibited higher collectivism and more situational/less dispositional attribution than the nonmigrants, which was expected given previous cross-cultural comparisons of South Asian and Western countries (Oishi, 2000). As before, this discounts any immediate and complete shift. The second-generation U.K.-raised British Bangladeshis were intermediate between the two groups on these measures, replicating the partial shift observed in second-generation Asian Americans, and suggesting a mix of parental/heritage and nonparental/nonheritage influence.

Going beyond simple between-generation and between-group comparisons, we also used model-comparison techniques developed within ecology (Burnham & Anderson, 2010) to compare the predictive power of specific transmission pathways for different measures. Model comparison weights the evidence for different theoretically derived models to avoid the weaknesses of null hypothesis testing and an overreliance on p -values (Cumming, 2013). Individualism and dispositional attribution were predicted largely by markers of horizontal and local-oblique cultural transmission, including country of respondent's birth, U.K.-based mass media exposure, and years of formal education. Collectivism, social closeness, and situational attribution, on the other hand, were predicted mostly by markers of vertical or heritage/oblique cultural transmission, including country of parents' (but not participants') birth, religiosity (which in our sample was much higher in the Muslim British Bangladeshi community than in the nonreligious, nonmigrant groups) and frequency of family contact, and secondarily by horizontal cultural transmission. If generalizable to other populations, then these dynamics might explain the aforementioned patterns of cultural macroevolution. We might posit that individualism has increased, while collectivism has changed little in both the United States and Japan (Hamamura, 2012), because the former is transmitted horizontally and therefore changes rapidly, while the latter is transmitted vertically, therefore changing more slowly.

Further studies are needed to identify more precisely the transmission pathways responsible for maintaining cultural variation in psychological processes, and for causing cultural change in those cases in which change has been documented. As noted, migrants are a particularly good seminatural experiment for doing this, as parental and heritage/oblique influences on the one hand, and local/oblique and peer influences on the other, are disassociated. But longitudinal studies (e.g., Greenfield, Maynard, & Childs, 2003) will also be useful for tracking actual change over time, particularly within and across generations of migrants as they acculturate, rather than relying on cross-sectional snapshots. Model comparison statistics may be borrowed from ecology (Burnham & Anderson, 2010) to go beyond testing single predictors against vague null hypotheses at an arbitrary level of significance, and instead assess the relative strength of evidence for different transmission pathways. Further analyses should go beyond our initial attempts (Mesoudi et al., 2016b) and test specific models of horizontal cultural transmission, such as prestige bias or conformity (see [Figure 5.1e–g](#)). Existing quantitative models of cultural evolution provide a useful starting point.

TESTING ULTIMATE EXPLANATIONS FOR THE ORIGIN OF CULTURAL VARIATION

While transmission pathways and social learning biases concern the proximate means by which cultural variation is transmitted and changed from one generation to the next, a complementary question concerns the ultimate origins of that cultural variation. Historical evidence suggests that psychological differences have roots in the distant past, with contemporary dimensions such as individualism–collectivism and analytic–holistic cognition found in the ancient philosophical modes of thought of Ancient Greece and Ancient China (Nisbett et al., 2001). Assuming that these traits are not genetic (and as seen in the previous section, migration data suggest that they are not), these psychological traditions may be seen as examples of long-term cultural macroevolution, much like long-term language lineages and tool-use traditions. As such, we may ask: What were the cultural

evolutionary selective pressures that gave rise to these different systems of thought?

Several hypotheses have been proposed to explain the origin of psychological differences. Only one of these, to my knowledge, has been directly inspired by cultural evolution theory. Chang et al. (2011) argued that East–West differences in psychological dimensions (e.g., collectivism–individualism, interdependence–independence) arose as a result of different weightings given at a society level to social and individual learning. As noted earlier, theoretical models suggest that neither social nor individual learning alone is an effective means of adaptation; instead we should expect a mix of both (Boyd & Richerson, 1995; Enquist et al., 2007). Yet the precise mix should depend on various factors. One factor that has received much attention is the rate of environmental change. Stable environments favor relatively more social learning, as other people’s knowledge will remain relevant, while unstable environments favor more individual learning, as others’ knowledge may become outdated (Aoki & Feldman, 2014; Aoki et al., 2005). Chang et al. (2011) applied these insights to East–West psychological differences. The primary societal means of cultural adaptation in the East (primarily China), they argued, was weighted toward social learning. This was and is reflected in, for example, stronger social ties and social interdependence, greater respect for elders and conformity to social norms, and more rote learning and less innovation in educational systems. The primary means of adaptation in the West (primarily Western Europe), meanwhile, was and is individual learning. This was and is reflected in weaker social ties, less rigid following of elders and existing social norms, more innovation in science and technology, and encouragement of creativity and independent thinking in educational systems. In a recent direct test of this, Mesoudi, Chang, Murray, and Lu (2015) found higher rates of social learning in a computer-based artifact-design task in people from mainland China, compared to participants from the United Kingdom, as well as Western-exposed Chinese students in the United Kingdom and a sample from Hong Kong (see also Bond & Smith, 1996).

Chang et al. (2011) argued that these different learning styles are in turn related to environmental differences. They pointed to evidence showing greater instability and fluctuation in Western Europe than in China in domains such as climate, governance, migration, warfare, agriculture, and

pathogens over the last several thousand years. For example, 19 of the worst recorded famines and droughts occurred in Europe, while China has only experienced nine; China has experienced political unity over most of its 2,000 year history, while Western Europe has long been much more politically and linguistically diverse, with frequent conflict and exchange of territories. While Chang et al.'s hypothesis needs further testing, particularly to quantify and formally test the historically different rates of environmental change, this proposal has the benefit of stemming from theoretical modeling work within cultural evolution that has received independent empirical support.

Other suggested ultimate explanations for the origin of psychological differences relate to means of subsistence. Nisbett et al. (2001) suggested that Western analytic thinking arose in ancient Greece as a result of the solitary herding, hunting, and fishing common in the mountainous and coastal terrain of this region, while East Asian holistic thinking arose in ancient China as a result of farming, and particularly rice farming, which necessitates more communal coordination and closer social ties. Uskul, Kitayama, and Nisbett (2008) provided support for this hypothesis by showing that Turkish farmers and fishermen who all work closely together show more holistic and less analytic thinking than herders from the same region, who typically work alone. Talhelm et al. (2014; Talhelm & Oishi, [Chapter 4](#), this volume) argued for more fine-grained differences within the “farmers” category, showing that regions of China with a history of rice farming are more collectivistic than regions with a history of wheat farming, because the latter requires less social cohesion than labor-intensive rice farming.

Other hypotheses consider demographic factors rather than means of subsistence. Kitayama, Ishii, Imada, Takemura, and Ramaswamy (2006) suggest that frontier regions foster independence, analytic thinking, and individualism due to their lawlessness and environmental uncertainty, by showing that residents of the more recently settled Japanese island of Hokkaido are higher on these measures than people from other parts of Japan with no recent history of being on a frontier. Finally, Thornhill, Fincher, and colleagues have linked psychological differences to historical levels of pathogen exposure, arguing that the close social ties and distrust of outsiders found in highly collectivistic (e.g., East Asian) societies emerged as

a means of protecting the ingroup from dangerous pathogens brought by members of outgroups, to which ingroup members would not have evolved immunity (Fincher & Thornhill, 2012; Fincher, Thornhill, Murray, & Schaller, 2008). Support comes from positive cross-country correlations between collectivism and historical levels of pathogen prevalence (Fincher et al., 2008).

All of these hypotheses appear plausible, and all have some degree of support. They may also not be mutually exclusive: Kitayama et al.'s (2006) frontier theory possibly overlaps with Chang et al.'s (2011) environmental change theory given that frontiers by definition are associated with environmental novelty and uncertainty, which is predicted to favor stronger individual learning and therefore individualism. However, there is great opportunity to use cultural evolution methods to more rigorously test all of these hypotheses. One major methodological problem is the lack of correction for shared cultural descent when conducting multicountry correlations, known in anthropology as “Galton’s problem” (Figure 5.2). Fincher et al. (2008), for example, found significant correlations across several countries between individualism–collectivism and pathogen stress. Yet cultural evolution researchers have long pointed to the problems of conducting correlations that treat countries as independent data points, which is seldom the case due to shared cultural history (Mace & Pagel, 1994). Treating, say, the United Kingdom, the United States, and Australia as independent data points is dubious given their intertwined cultural histories (Currie & Mace, 2012; Pollet, Tybur, Frankenhuys, & Rickard, 2014). Phylogenetic analyses were developed by biologists to solve the equivalent problem in biology, in which species are not statistically independent due to shared genetic descent (Felsenstein, 1985; Harvey & Pagel, 1991). The same methods may be used to control for shared cultural descent in cross-country comparisons to provide a more robust test of the aforementioned hypotheses, typically using language as a proxy for cultural relatedness (Mace & Holden, 2005; Mace & Pagel, 1994). Various methods are used to reconstruct cultural phylogenies, including maximum parsimony, which minimizes the number of changes along the branches that are needed to recreate the observed cultural variation, through to more sophisticated Bayesian Markov Chain Monte Carlo (MCMC) methods, which provide

explicit priors regarding the likely direction of evolutionary change (Matthews, Tehrani, Jordan, Collard, & Nunn, 2011; Pagel, 2009).

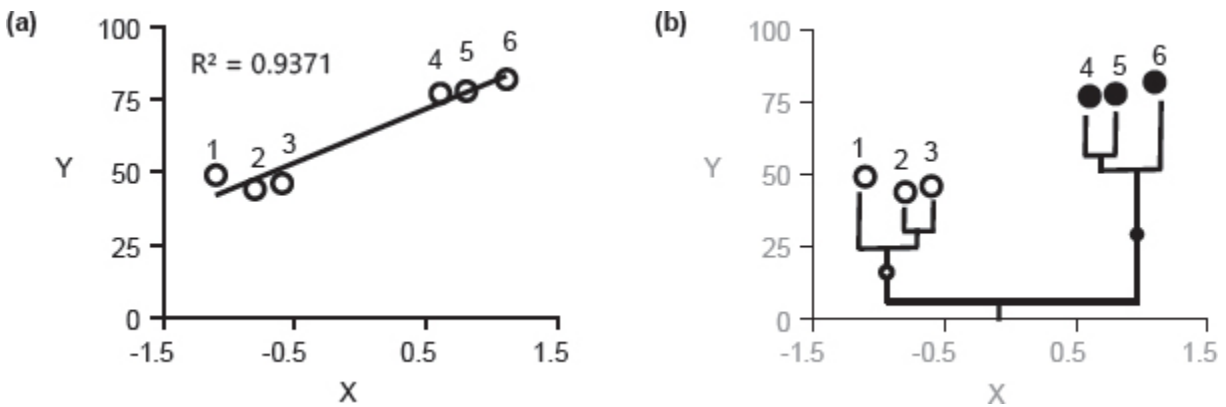

FIGURE 5.2. Apparently strong cross-country correlations can be artifacts of shared cultural descent. The graph in (a) shows a strong correlation across six countries (1–6) between Y (which might be, for example, collectivism) and X (which might be, for example, pathogen exposure). Yet as shown in (b), it is inappropriate to treat these as six independent data points if countries 1–3 share a common cultural ancestor that happened to have low Y (unfilled circles), and countries 4–6 share a common cultural ancestor that happened to have high Y (solid circles). We now have only two independent data points, making the link between X and Y much more tenuous.

A second problem is that many of these hypotheses about the origin of cultural variation in psychological processes are expressed as verbal, informal historical narratives rather than formal mathematical or simulation-based models that are amenable to precise testing. Turchin (2003, 2008) has argued that despite the traditional reluctance of historians to quantify their hypotheses about historical phenomena, or to posit general mechanisms that operate across multiple societies and time periods, actually such an endeavor is entirely possible—and hugely beneficial—by using modeling techniques borrowed from evolutionary biology and ecology. For example, Turchin (2003) used population dynamic models from ecology to explain the historical rise and fall of empires in Europe according to a small number of explicit assumptions, primarily the group-level trait of social cohesion (named *asabiya* by the medieval sociologist Ibn Khaldun) and its effects on long-term societal dynamics. Turchin argued that small social groups in frontier regions at the edges of larger empires have high *asabiya* and intense within-group cooperation due to their small size and common enemy (the empire). This makes them more effective in intergroup

competition, as their members are more likely to work together, fight together, contribute to common goods, and so forth. These small groups grow larger via conquest of smaller neighbors, and eventually conquer larger empires, which have lower *asabiya* due to their large size and problems of free-riding elite classes. The conquerers themselves therefore become an empire, yet as they grow larger, *asabiya* drops again due to free-riding elites. This allows smaller frontier regions with high *asabiya* to successfully invade the larger empires, and the cycle continues over time. Turchin (2003) expressed all of this in mathematical terms using models originally applied to predator–prey cycles in ecology, derived specific quantitative predictions for the turnover of empires, and demonstrated that these predictions are supported by the best available historical data on the rise and fall of empires (see Turchin et al., 2013, for a more geographically explicit simulation model of similar historical dynamics).

There is great opportunity to do the same for the aforementioned historical explanations for psychological variation. Indeed, Turchin and Ibn Khaldun’s concept of *asabiya* resembles the collectivism or interdependence seemingly captured by many psychological constructs. Yet Turchin suggests the opposite of what was suggested by Kitayama et al. (2006): Turchin argues that frontier regions should be high in *asabiya* because they are united by a larger enemy, whereas Kitayama et al. suggest that they should be low because of the lack of governance. These very different hypotheses may be pitted against one another by (1) converting Kitayama et al.’s verbal hypothesis into a quantitative model, with assumptions about, say, individual- and group-level competition, harshness of the environment and the presence–absence of institutions; (2) comparing this quantitative frontier model with Turchin’s *asabiya* model to see whether they make contrasting quantitative predictions (e.g., about the rate of group turnover, or expected geographical variation in groups of different sizes); and (3) comparing these contrasting predictions/models to quantitative historical data, ideally using the model-comparison techniques discussed earlier, which give likelihood of support for each model (e.g., Akaike weights) rather than testing each model separately against a meaningless “null model” using *p*-values (Burnham & Anderson, 2010).

Finally, previous studies have simulated historical or prehistoric patterns of technological change in the laboratory, in order to gain insight into the

individual-level processes that generate population-level (e.g., archaeological) change (Kempe, Lycett, & Mesoudi, 2012; Mesoudi & O'Brien, 2008; Morgan et al., 2015; Schillinger, Mesoudi, & Lycett, 2014). For example, Mesoudi and O'Brien (2008) showed that patterns of arrowhead variation documented in the archaeological record are consistent with different learning dynamics: Prestige bias reduces artifact variation in experiments (and, by extension, in the archaeological record) as a single successful demonstrator's design is copied, whereas individual learning increases variation as different people arrive at different designs. There is opportunity to conduct experimental simulations of the aforementioned historical hypotheses for psychological differences. Participants might, for example, conduct tasks designed to simulate different means of subsistence (e.g., rice vs. wheat farming) or the social connectedness entailed in each, to see whether psychological processing is shifted in the predicted direction. This assumes that such characteristics are flexible enough to be primed in this way, as suggested by previous studies (Oyserman & Lee, 2008; Oyserman & Yan, [Chapter 20](#), this volume). An initial study taking this approach (Magid, Sarkol, & Mesoudi, 2017) failed to find any effect of different activity patterns on culturally variable cognitive measures, although there is much scope for further tests.

CONCLUSION: PLACING CULTURAL PSYCHOLOGY WITHIN AN EVOLUTIONARY SCIENCE OF CULTURE

I have argued here that numerous links may be drawn between cultural psychology and the burgeoning, interdisciplinary field of cultural evolution. The two fields are highly compatible: Cultural evolution researchers assume that the major means of human adaptation is cultural rather than genetic, due to our capacity for high-fidelity social learning that supports cumulative culture and long-lasting lineages of cultural descent. According to this perspective, it is not surprising that cultural variation has emerged in human psychological processes. Yet this does not necessitate a culture versus biology dichotomy that has pervaded the social sciences and humanities for much of their history, in which evolution is assumed to be irrelevant to

human behavior. Instead, culture can be placed within an evolutionary context, with models and cross-species comparative evidence speaking to the reasons why culture evolved in the first place, its evolutionary function, and which of its aspects are uniquely human, and which are shared by other species. Moreover, cultural change may itself be analyzed as an evolutionary process that shares fundamental characteristics with biological/genetic evolution. Consequently, powerful methods, tools, and concepts may be borrowed from biology, suitably modified where appropriate, to analyze and explain cultural change, such as mathematical modeling techniques for linking individual-level behavior to population-level patterns, or phylogenetic methods for reconstructing history. And one of the major benefits of the field of cultural evolution is its interdisciplinarity, linking those branches of the social sciences concerned with individual-level behavior (e.g., psychology, microeconomics, neuroscience, ethnography) with those concerned with population-level patterns of behavior (e.g., archaeology, history, macroeconomics, comparative sociology) (Mesoudi, 2011; Mesoudi, Whiten, & Laland, 2006). Cultural psychology can provide an important link between these two levels by exploring the influence of large-scale cultural variation on individual-level psychological processes, and vice versa.

In turn, cultural psychologists can offer valuable guidance on some of the hypotheses, models, and empirical tests constructed by cultural evolution researchers. It is typically assumed in cultural evolution models, for example, that people everywhere exhibit the same social learning, conformist, or prestige-biased tendencies, and often that such tendencies are genetically inherited and subject to natural selection. While this may in many cases be a convenient modeling simplification, it is clearly not realistic given evidence for cultural variation in learning biases (Bond & Smith, 1996; Mesoudi, Chang, Dall, & Thornton, 2016a; Mesoudi et al., 2015), and models are needed that allow for the acquisition of learning biases from others (e.g., Acerbi, Enquist, & Ghirlanda, 2009; Ghirlanda, Enquist, & Nakamaru, 2006). Cultural psychologists also have rich data on how social ties and relationships vary in different groups, which may be useful for models of cultural group selection (Richerson et al., 2016) and concerns the selection of group-level variation and the spread of group-beneficial traits.

In summary, there is much potential for mutual transfer of ideas between cultural evolution and cultural psychology.

ACKNOWLEDGMENTS

I am grateful to Dov Cohen and Shinobu Kitayama for valuable comments on an earlier version of this chapter, and to the U.K. Economic and Social Research Council (Grant No. ES/J01916X/1) for funding.

CHAPTER 6

Methods in Cultural Psychology

Dov Cohen

The chapter covers the four basic social science issues of causation, operationalization, sampling, and interpretation (COSI): “Do I know what is causing what?” (causation); “Am I measuring or manipulating what I think I am measuring or manipulating?” (operationalization); “How do my results generalize?” (sampling); and “Am I getting the big picture right and interpreting the data correctly?” (interpretation). In cross-cultural work, methods and theory are intertwined. Our research questions should dictate our methods, but sometimes the reverse is true, as researchers choose a method that leads them to implicitly adopt a certain view of culture. Thus, different methodologies locate causality inside the person, out in the world, or in the interaction between person and environment. Different sampling methods make different assumptions about what is culture and what is confound. They orient us toward viewing culture holistically or in terms of specific practices or causal forces. Different operationalizations derive from different assumptions about how well cultural constructs can be articulated, whether they play out similarly across cultures, and how they are best observed. In interpreting data, cultural similarities or differences “pop out” at us like the dimensions of a Necker cube, depending on our perspective. We also understand data through what our methods and biases foreground, but we can ask how other disciplines would interpret the data we did—and did not—collect.

Cultural psychologists who approach phenomena from, say, a social-psychological, developmental, or anthropological perspective not only inherit all the methodological problems and issues from their home disciplines, but they acquire many new ones. Studying a topic in more than

one culture brings some special complexities. Furthermore, some standard methodological problems that are largely ignored in one's home discipline (e.g., subject sampling) become major issues in cultural-psychological research. In contrast, very few (or perhaps no) methodological problems become easier when culture is added to the picture.

This chapter attempts to make explicit some of the methodological issues that pose extra challenges for culture researchers. As with other research, the methodological challenges center around four themes: causality, operationalization, sampling, and interpretation (COSI). In brief, these four themes involve the questions: "Can I determine causality?"; "What is my independent variable 'doing' to people, and/or what does my dependent variable actually measure?"; "To what populations can I generalize my results?"; and "Am I reading the data correctly?" (see summary in [Table 6.1](#)).

TABLE 6.1. COSI: Chapter Summary

The four basic issues of causation, operationalization, sampling, and interpretation all get harder in cross-cultural research. In either top-down or bottom-up cross-cultural work, nuts-and-bolts issues (operationalization and sampling) are implicitly tied up with more abstract issues of causation and interpretation. Our methods have implicit theories of culture built into them.

Causation

1. Descriptive studies—in which outcome variables tautologically follow from the cultural dimensions we are examining—are important.
2. Because culture is not randomly assigned, comparisons between cultural groups are correlational and can only be suggestive about causation, though those suggestions can be stronger or weaker.
3. Studies making claims about causation are affected by the choice of cultures sampled. For example, our conclusions about what collectivism is associated with would look very different if samples were not West (United States, Europe) versus East (Asia) but instead North (United States) versus South (Latin America).
4. Researchers can locate causality in the heads of individuals, in situations, or in interactions of person and situation. Examining culture \times situation, culture \times person, and culture \times person \times situation interactions can flesh out the different cultural logics that animate different cultures.
5. Macrocultural questions ultimately need macrocultural data, but can be usefully supplemented by (a) close comparisons and (b) experiments that re-create presumed causal effects in the lab.
6. Functionalist assumptions about cultural adaptations are a sensible place to start but are often wrong and need to be examined.

Operationalization

1. Cultural psychologists face the challenge of creating variables that are convincing and interpretable when seen through (at least) two cultural lenses.
2. Issues of translation, reference groups, and differential response biases need to be considered, though there are techniques that can lessen some concerns.
3. Specificity in measures can reduce noise and bias about a particular set of variables, but researchers must beware of imposing false etics.
4. Surveys that cast a wide net but have pallid questions and experiments that create engaging and “just right” situations both have problems but can usefully complement each other. Neuroscientific data can complement each type, and the export value of cultural psychology as neuroscientists try to “map out the *human* brain” may be huge.
5. Field experiments (on citizens, elites, and institutions), analyses of cultural products, and qualitative methods are part of cultural psychology’s pluralistic methodological repertoire.

Sampling

1. All generalizations—from probability and nonprobability samples—require some judgment and background knowledge so researchers don’t overgeneralize or overlocalize.
2. Convenience samples—regardless of size—have the unsolvable problem that one does not know who to generalize to.
3. Nevertheless, some sampling techniques can be informative. Typicality versus minimal difference sampling or expert versus inversion sampling are useful for different purposes (capturing a cultural Gestalt, identifying effects of specific practices and forces, examining “pure” idealized types).
4. Sampling college students, ethnic groups within versus between countries, and MTurkers are all special cases of the above and have their own strengths and weaknesses to consider.

5. Sampling techniques implicitly have theories of culture built into them (about what is culture and what is confound, grand vs. little traditions, the existence of “pure” types, etc.).
6. The “replication crisis” represents an opportunity for cultural psychologists, because our field is “anti-fragile.” Ultimately, we need to be able to measure or manipulate presumed cultural moderators.

Interpretation

1. A cultural psychology that integrates and differentiates is a richer field.
 2. With the Necker cube of culture, similarities and differences are embedded within each other, and the similarities or the differences “pop out” at us, depending on our perspective.
 3. A mental checklist and thought experiments—considering institutions, intermediaries, supply-side explanations, and design explanations—can help us identify our disciplinary biases.
 4. Explanations are best supported by converging evidence across methods, in which the strengths of some methods offset the weaknesses of others.
 5. Data may not converge, however. This may be due to sampling variability or to artifacts. Or data may not converge for substantively interesting reasons that revolve around the social, interactive nature of human action.
-

The mission of cultural psychology is to understand the different cultural logics that organize our social worlds. That understanding can make the unfamiliar familiar and the familiar strange—a potentially important move for improving understanding and softening judgments of the Other in our increasingly pluralistic world.

This chapter is not an exhaustive list of issues we face, and it does not cover qualitative research. Rather, it explores the four COSI areas by examining some issues within each that get especially knotty when we collect data cross-culturally. Lewontin (1995) observed that scientists spend a great deal of time talking about methodological issues to which their field has cogent answers, and ignore issues for which they do not. This chapter covers some of both types of issues.

ROUTES AND RUBS

In general, cultural psychology has tended to develop through (at least) two different routes: through (1) top-down ideas gleaned from ethnographic and historical studies, personal experience, and prior research, and (2) through bottom-up ideas stemming from failures to replicate—though sometimes these are “failures to replicate” via thought experiment, such as when a researcher looks at a study in mainstream psychology and says, “That would never work among (Group X).”

Top-Down Route

If the first route is followed, questions start with issues of operationalization and causation. The origin of the work may be some vaguely defined phenomenon described in the nonpsychological scholarly literature. Examples include (1) the individualistic versus group-oriented tendencies of Eastern versus Western cultures; (2) the curious pattern that the U.S. South has for years had the country's highest homicide rates, an effect that could be due to a concern with honor, the South's greater poverty and inequality, the legacy of slavery, hotter temperatures, a higher rate of gun ownership, or any of dozens of other factors; or (3) the hazily defined idea that Easterners think "holistically," whereas Westerners think "analytically" (an insight embodied in cryptic comments such as "Westerners think in a line, Easterners think in a circle"; Nisbett, 2004).

The first step is establishing the phenomenon. Exactly what does it mean to say that Easterners think "holistically" and Westerners think analytically? Exploring this means operationalizing these vague ideas—does it mean that Westerners will follow logical reasoning even if it leads them to conclusions that are wrong or violate what they know from experience? Yes (Norenzayan, Smith, Kim, & Nisbett, 2002)? that Westerners view time as a progressive march moving in one direction, whereas Easterners see time as embodying recurring cycles in which events oscillate or repeat patterns of the past? Yes, (Ji, Nisbett, & Su, 2001)? that Westerners are more likely to explain behaviors in terms of a person's character, whereas Easterners explain behaviors in terms of situational forces? Sometimes—it depends on the salience of the situation and the diagnosticity of behavior (Choi, Nisbett, & Norenzayan, 1999; Miyamoto & Kitayama, 2002).

However, questions of causality and interpretation are never far behind, because they implicitly drive important nuts-and-bolts issues of operationalization ("What do I measure or manipulate?") and sampling ("What populations do I compare?"). Thus, if I think Eastern holism derives from the spiritual ideas of Taoism or Buddhism, I pick different populations to compare and different variables to measure and manipulate than if I think Eastern holism derives from social patterns of interdependence (vs. independence). Or if I think North–South differences in violence are driven by a concern for honor, I run very different studies than if I think they are

driven by temperature or a legacy of slavery, both in terms of populations from which I sample and the manipulations or measurements I use. As noted in the section on interpretation, our implicit ideas about causality (what is the driving force “behind” a phenomenon) affect where we look for answers—and where we do not.

Bottom-Up Route

If the route into cross-cultural work starts from the bottom-up, it may begin with a simple failure to replicate—though, as noted, many of these failures to replicate are initially *thought experiments*, such as when a researcher looks at a study and thinks, “That would never work in Japan.” Superficially, the main operationalization issue seems solved (my measures or manipulations should be the same as the original study). But, quickly, other sampling and operationalization issues flood in: What groups do I compare so the study will be maximally informative (sampling)? How can I be sure the measures and manipulations will be comparable in the two cultures (operationalization)?

Causality and interpretation issues will not be far behind and will suggest other nuts-and-bolts features of study design. *Why* would the effect never replicate in Japan? What are the ways of understanding the world (the cultural logics) that make a behavior sensible to group *X* and the opposite behavior sensible to group *Y*? Anthropologist Mel Spiro, paraphrasing T. S. Eliot, said the study of culture should make the strange familiar and the familiar strange. Doing so requires (1) bridging the empathy gap to see what makes another culture’s way of seeing the world sensible, or at least comprehensible and coherent, and (2) stepping back and overcoming our own naive realism to see that our taken-for-granted way of seeing the world is just *one* way of doing so.

The Rub

The COSI issues seem straightforward enough. But as will be described, they get complicated pretty quickly. Am I understanding what is causing what? Are underlying differences in individualism–collectivism driving some

cultural difference? Perhaps, but our understanding of the effects that individualism and collectivism produce will be very different if our comparisons go East versus West (collectivist Asia vs. individualist North America) as opposed to North versus South (individualist North America vs. collectivist Latin America). Other complications: Unless I want to consider *any* difference between cultures as a “cultural” difference, how do I decide what is culture and what is a confound? What does it mean to say that culture exists as a causal force “out in the world,” and how would I measure it? There are also balancing acts and trade-offs required as we begin research: Start with experiments that are narrow in focus but vivid and engaging versus questionnaires that are wide in focus but often pallid? And then there are unsolvable problems that we simply have to do our best with, such as (1) correlation is not causation, but membership in cultural groups is not randomly assigned, or (2) if I do not have a random sample, I cannot know what population my results generalize to (and even with a random sample, subjective judgment is required, so that I neither overgeneralize nor overlocalize).

Our methods can never be bulletproof. But they can be more appropriate or less appropriate for the questions we ask, and the answers they provide can be better or worse.

Below, I discuss the COSI issues. As will be seen, the divisions between the four COSI categories are blurry, as one issue bleeds into another. We conceptually separate them here for organizational purposes, noting links along the way.

CAUSALITY

This section covers three main issues with which cultural psychologist must wrestle, including how we think about cultural dimensions underlying difference, where we locate “culture” as a causal force, and macrocultural questions of historical or ecological circumstances that create cultural difference.

Leaving Terra Firma

Any study without a randomly assigned independent variable is definitionally a correlational study and can therefore never prove causality. The vast majority of studies in cultural psychology fit into this correlational category, because culture is not a manipulated variable. We make statements such as “The Japanese were more likely to emphasize duties and the Americans more likely to emphasize rights, *because* Japanese and American cultures differ in how they view the individual and the collectivity” or “Cultures *A* and *B* value harmony, *because* their agricultural practices require them to work together.” These claims can be only suggested by our data. Nevertheless, many studies make such causal claims, and using solid methodology often makes the difference between a strong suggestion of causality and a weak one.

Descriptive Studies

Studies in cultural psychology are often of the form: Culture 1 has cultural syndrome *X*, whereas Culture 2 has syndrome *Y*. (Or, sometimes, Culture 1 has syndrome *X*, whereas Culture 2 does not.) Examples of this are studies showing that Eastern cultures tend to be more collectivist, whereas Western cultures tend to be more individualist, or that the U.S. South has a culture of honor, whereas the U.S. North does not (or has a culture of “dignity”) (Uskul, Cross, Günsoy, & Gul, [Chapter 30](#), this volume).

These studies may be purely descriptive, outlining cultural patterns in one society versus another. The measured variables tend to be face-valid representations of the cultural difference one is studying. So a researcher may offer evidence that Mexican culture is more collectivist than American culture by showing that Mexicans and Americans differ on an individualism–collectivism scale, that they think about and behave toward ingroups and outgroups differently, or that they differ in how much they identify with their ingroups. Such evidence is descriptive, because the measured (or “outcome”) variable flows tautologically from the definition of individualism and collectivism. Furthermore, a researcher might conduct studies that explore a given cultural characteristic in depth, examine how this characteristic manifests itself across societies, or study how cultural characteristic *X* is related to cultural characteristic *Y* (without worrying

about causal direction; Markus & Kitayama, 1991; Shweder, 1997). In such descriptive studies, no causal claims are made. As Rozin (2001; see also Becker, 2008) notes, these studies are often a sensible place to start. More mature sciences (e.g., biology) began this way and still devote considerable attention to description. Rozin argues that social psychologists, because of their status anxiety, have too quickly scanted important phenomena in need of basic descriptive work to build impressive formal models of less important phenomena. Cultural psychologists also may face the same temptation.

Causal Claims

Many studies attempt to be descriptive *and* to make a causal claim. They often are of two kinds: (1) Culture 1 has syndrome *X*, whereas culture 2 has syndrome *Y* because of reason *R*, or (2) cultures differ in some local domain *D*, and these differences derive from some greater underlying difference in major cultural syndromes. Causal claim 1 is a macrocultural claim and tends to be rarer among cultural psychologists, so discussion of it is temporarily postponed.

Differences in Local Domain D Come from Deeper Differences in Underlying Syndromes X or Y

This type of causal claim is often made more or less implicitly. Examples include East–West differences in approach versus avoidance motivation derive from more general differences in independence versus interdependence; or Korean versus Canadian differences in leadership style derive from underlying differences in holistic versus analytic thinking style; or U.S. Southern versus Northern politeness patterns differ because of the presence or absence of a culture of honor; and so on. These studies are “causal” (rather than “merely” descriptive), because the measured outcome variable does *not* tautologically derive from the definitions of the deeper cultural syndromes.

A crucial issue involves identifying the underlying dimension. At times, these claims may seem to derive from the famous “principle of the drunkard’s search.” The name comes from a joke about a man outside a bar who is looking for his keys under the lamppost. He knows the keys probably are not there, but that is where the light is good, so that is where he looks. A potential pitfall for researchers is to look for the underlying causal dimension for a phenomenon in a place where the light is already shining and the territory is well-illuminated.

Researchers such as Triandis, Hofstede, Markus, Kitayama, Bond, and others have shined a bright light on cultural syndromes of independence versus interdependence or individualism versus collectivism. Thanks to their work, we know a great deal about these syndromes, and it has become a very salient way to describe cultures. However, there is a methodological problem if one relies too much on this individualism–collectivism difference for causal explanations. For example, one might make the following causal claims: Collectivist cultures tend to have inhibitory display rules, downplay emotionality, or prefer low-intensity emotions (Ford & Mauss, 2015), experience more negative affect, have lower self-esteem, and be more avoidance-oriented compared to individualist cultures, which are more expressive, show higher positive affect and self-esteem (Tsai & Clobert, [Chapter 11](#), this volume; Tsai et al., 2016), and are more approach-oriented.

These may all be true, but two issues should give us pause. The first is that cultures differ on any number of dimensions, in addition to the individualist–collectivist difference. China and the United States differ, for example, not just on individualism–collectivism but on how tight versus loose they are (Gelfand et al., 2011), how fatalistic, how egalitarian, how religious, how ethnically homogenous, and so on (as well as on many “noncultural” demographic factors—a topic addressed later). A general readiness to attribute a difference between an Eastern and a Western culture to individualism–collectivism reflects a tendency to rely (and overrely) on this single, well-explored dimension instead of on many other underlying cultural dimensions that may be causally relevant.

Second, consider that much, though not all, individualism–collectivism work has gone in the East–West direction, sampling countries from North America (individualist) versus East or South Asia (collectivist). Imagine instead what might have happened if the work had instead gone North–

South, sampling countries from North America (individualist) versus Latin America (collectivist). A number of conclusions about the way collectivist versus individualist cultures are might be reversed. We might conclude, for example, that collectivist cultures are happier (controlling for income effects), express more affect and assign greater significance to emotion, are more extroverted, prize passionate over companionate love, have looser situational norms and standards of behavior, are less moralistic and more tolerant of human foibles, and so on, compared to individualist cultures (Campos & Kim, 2017; Tov & Diener, 2007; Franiuk, Cohen, & Pomerantz, 2002; Hatfield, Rapson, & Martel, 2007; Holloway, Waldrip, & Ickes, 2009; Kitayama & Salvador, 2017; Sanchez-Burks & Lee, 2007; Rohter, 2000; Ruby, Falk, Heine, Villa, & Silberstein, 2012; Scherer, 1997; Torelli, Leslie, Stoner, & Puente, 2014; Levine, Harrington, & Uhlmann, [Chapter 23](#), this volume; Uhlmann & Sanchez-Burks, 2014). The bias in how we have sampled individualist and collectivist cultures has led to certain conclusions about the way individualist and collectivist cultures “generally” are, and these conclusions might be reversed had researchers taken Latin America as their collectivistic prototype rather than East Asia.

There are at least two ways to think about what sorts of patterns different cultural syndromes give rise to, and these have very different implications for our methodologies. One way is to think in terms of “necessary” or “contingent” (probabilistic) facts (Braudel, 1980). In the search for necessary or contingent facts, we would look for the cultural syndromes that either necessarily or probably lead to certain behavior patterns. For example, individualist cultures tend to have more gender equality than collectivist cultures, because the sanctity of the person in individualist cultures overrides ascribed status or social roles. Or collectivist cultures use shame as a socializing tool, whereas individualist cultures are more likely to use guilt, because shame involves caring about others’ approval, whereas guilt involves self-judgment and needs no audience. In research focused on necessary or probabilistic facts, a diverse sample of cultures is needed so that one can avoid sampling biases of the type just described. One may have to sacrifice depth for breadth, gathering data from as many cultures as is feasible, glossing over the particularities of any one culture to find out what is “generally true” of, say, individualist or collectivist cultures.

A second way to think about cultures is in terms of multiple equilibrium states. Although acknowledging that probabilistic facts exist, this way of thinking about culture would focus more on how the pieces of culture fit together in a rough equilibrium in a particular context. In this is also an acknowledgment that many different equilibria might exist—that there is more than one way to be a collectivist culture or an individualist culture, for example. This approach suggests a deep dive into a more limited set of cultures, sketching out the practices, meanings, and worldviews that give coherence to the particular cultures under study.

Locating Causality: Mind-Sets, Individual Differences, Situations, and Cultural Logics

A second issue about causality—where we locate causal forces—also illustrates how closely theory and method are tied together. In our decisions about what to measure or manipulate, we are implicitly making claims about where culture’s causal force lies.

Social-cognitive approaches have typically relied on priming methodologies, highlighting the role of construal, as putting people in certain mindsets leads them to understand stimuli and react to them in certain patterned ways. Work in this vein has suggested that priming social interdependence, for example, makes both Westerners and Asians more prevention-focused in their goals (Lee, Aaker, & Gardner, 2000), more generous in social comparisons (White, Lehman, & Cohen, 2006), and more holistic in thinking style (Kuhnen & Oyserman, 2002; Masuda, Russell, Li, & Lee, [Chapter 8](#), this volume).

Individual-differences approaches examine culture the way a traditional personality researcher might (see, e.g., Rentfrow & Jokela, [Chapter 29](#), this volume; Church, 2016). This method examines a cultural difference (in, say, holistic or analytic thinking styles) and tries to use mediation to show that individual differences in some underlying variable (say, having an independent or interdependent self-schema) account for the between-group difference in thinking style. The method has the advantage of explicitly considering within-culture variation, necessarily rejecting the idea that all members of a culture are homogenous with respect to some trait. However,

it does come with other theoretical baggage in that it firmly locates culture within individuals' personalities.

Situational approaches attempt to measure affordances out in the world that pull for certain types of behavior. One example of such an approach is “situation sampling,” developed by Kitayama, Markus, Matsumoto, and Norasakkunkit (1997; see also Boiger, Mesquita, Uchida, & Feldman Barrett, 2013). In this technique, respondents from different cultures are asked to generate situations in which a certain type of behavior or reaction occurred. These situations, which can be coded for frequency and recency, are then given to other participants from these cultures, who can judge the situations for various features, for example, how conducive they are to self-enhancement versus self-criticism (Kitayama et al., 1997), influence versus adjustment (Morling, Kitayama, & Miyamoto, 2002), or gain for the self versus the other (Savani, Morris, Naidu, Kumar, & Berlia, 2011). Situation sampling tries to actually measure cultural differences in situations that exist out in the world, rather than merely assert that such differences exist.

Situation sampling need not be done only through participant recall. Experience sampling studies (“beeper studies”) periodically “beep” or text people at random times on their phones, typically asking them to describe the situations they are in, who they are with, and how they are feeling (ex. Smith & Hofmann, 2016). Other wearable devices allow one to “listen in” on users' environments throughout the day (Mehl, Robbins, & Deters, 2012), and recording devices that visually capture a scene and where the participant is looking (e.g., Google Glasses) are not far behind (Dietze & Knowles, 2016).

Cultural Logics: Stacking CuPS

The previous approaches locate culture in social-cognitive construals or mindsets, chronic individual differences, and situational affordances. They also are often premised on the idea of a single cultural logic—that people in any culture with these construals, having these personalities, or confronting these situational affordances will behave the same way. However, if one believes that there can be different cultural logics animating different cultures or that different cultures are organized around different dominant

themes (or “syndromes,” as Triandis, 1996, calls them), then one is likely to take an *interactionist* approach to locating causality. CuPS—*culture, person, and situation*—stack into each other. Thus, cultural logics differ such that person-level variables mean something different in different cultures. And situations mean something different in different cultures, drawing forth different patterns of behavior. Hence, differences are located not just in different average levels of a trait or in different frequencies of situational affordances and primes, but in the interactions of culture, people, and situations. The CuPS stack into each other to form culture \times person, culture \times situation, and culture \times person \times situation interactions. Different cultures may be organized around different cultural logics, and the interaction effects allow us to flesh out these logics, helping to refine our understanding of the who, when, how, and why of cultural differences.

Culture \times Person Interactions

Differences in cultural logics may be illustrated with culture \times person interactions. For example, in some Asian cultures, interdependence means muting one’s emotions (particularly negative emotions) so as not to disturb interpersonal harmony. In other cultures, say, Latin America, emotions are the stuff of life; to be interdependent in those cultures means to express one’s emotions for others to share in, to be engaged with and fully reactive to others’ emotions, and to expect others to do the same. Asian and Latin American cultures have two different cultural logics about emotions and their role in interpersonal relations, and to capture this, one might look for culture \times person interactions, such that interdependence predicts, say, less emotional expression in Japan but more emotional expression in Brazil (Gallup, 2015, 2017; Ruby et al., 2012).

Another example of using culture \times person interactions to illuminate a cultural logic relates to an honor culture that embraces (1) an ethic of bravery and toughness, such that one is expected to use violence in response to insults and affronts, and (2) an ethic of virtue, such that one is expected to show prosocial reciprocity, trustworthiness, and so on, to relevant members of the ingroup (Brown, 2016; Uskul et al., [Chapter 30](#), this volume). In most contemporary cultures, violence and virtue do not go together, but in an honor culture they do. Thus, D. Cohen and Leung (2012) found that greater

martial honor (as indicated by military service or the lack thereof) predicts greater integrity and incorruptibility among political elites (presidents and politicians) from the U.S. South (an honor culture) but not among elites who come from outside the South (from non-honor-culture regions of the United States). Traits of physical courage and moral courage are packaged together in an honor culture. Outside an honor culture, they are clearly separable, and one may have little to do with the other.

Culture × Situation Interactions

Culture × situation interactions may also illuminate a cultural logic, in that they may show how different situations call forth different role behaviors in different cultures. For example, a culture × situation analysis might focus on how, in an individualistic, egalitarian culture, giving someone a *low* power position leads to anger (because the person has been subordinated and deprived of the right to be treated as an equal); in contrast, in a hierarchical, collectivist culture, giving someone a *high* power position might lead to expressions of anger (because expressing anger is a perk of high status, and because authorities can legitimately use anger as a tool for enforcing discipline) (Kitayama et al., 2015; Kuwabara, Yu, Lee, & Galinsky, 2016; Miyamoto, Yoo, & Wilken, [Chapter 12](#), this volume; Park et al., 2013).

Culture × situation approaches are also good for illustrating boundary conditions of when effects do and do not occur. Furthermore, they may be useful complements—or counterpoints to—culture × person approaches, because they may illuminate phenomena such as the “crowding in” of psychological attunement or the “crowding out” of strong situations undermining the internalization of values.

Crowding In: Psychological Attunement. A culture × situation approach may be helpful for examining processes of psychological attunement, in which people become sensitized to the tasks emphasized in their environment. Thus, for example, situations may generally pull for influencing others, and Americans may be especially attuned to opportunities for, and rewards of, jumping into such situations. Conversely, other situations may generally pull for adjusting to others, and Asians may be particularly sensitive to the opportunities and rewards of such situations (Morling et al., 2002; see also neuropsychological evidence for attunement as

a lifetime of learning sensitizes neural circuits in the brain; Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume).

Crowding Out: Undermining Internalization. A culture × situation approach need not imply psychological attunement and internalization, however. Interesting work by Yamagishi has shown the opposite for some behaviors. Instead of creating attunement and internalization, strong situational or institutional pressures can sometimes crowd out such tendencies. Thus, Yamagishi (1986, 1988; Yamagishi & Cook, 1993; Yamagishi & Hashimoto, 2016) and others have produced laboratory experiments examining in microcosm how “structural” factors—such as the presence or absence of a sanctioning system that punishes cheaters—shape people’s behavior. In examining the “free rider” problem, in which people shirk in contributing to public goods, Yamagishi (1988) contrasts two approaches: a cultural–individualistic approach and a cultural–institutional approach. The cultural–individualistic approach argues that behavior follows from internalized values; thus, collectivists will not free ride, because they value contributing to the group. The cultural–institutional approach argues that behavior follows from the cultural institutions that have been established, such that collectivists do not free ride, because systems of “mutual monitoring and sanctioning” are prevalent in collectivist societies.

One of Yamagishi’s contributions has been to take culture out of individuals’ heads and show the importance of institutional forces. More specifically, his studies have (1) provided evidence for the cultural–institutional approach by showing how various systems of exchange and opportunities to develop sanctioning systems affect people’s decisions to cooperate or free ride; and (2) provided evidence *against* the cultural–individualistic approach by showing that Japanese subjects are more likely than American subjects to exit from groups in which there is no system to monitor and punish cheaters. When strong situational or institutional forces are *too* salient, they may undermine the internalization of values that those forces are trying to instill (*à la* dissonance or overjustification; Aronson & Carlsmith, 1963; Lepper, Greene, & Nisbett, 1973) or they may lead people to believe that others’ behaviors are solely driven by those strong external forces and will not occur without such forces (*à la* attribution principles of

discounting; Kelley, 1973) (D. Cohen, 2015; D. Cohen, Liu, & Shin, in press; see also Lowes, Nunn, Robinson, & Weigel, 2015; Tabellini, 2008).

Overall, culture \times situation analyses may be useful in highlighting the way different cultural logics pull for different role behavior, examining processes of psychological attunement or crowding out, or simply exploring how cultural differences play out in more than one situation. They enrich straight situational approaches and complement (“crowding in” effects) or counterpoint (“crowding out” effects) individual-difference approaches.

Culture \times Person \times Situation Interactions

More complex designs involve stacking the CuPS into three-way interactions. Mischel, Mendoza-Denton, Shoda, and colleagues have discussed the notion of “behavioral signatures,” or characteristic individual differences that emerge within particular situations (person \times situation interactions; Mendoza-Denton & Mischel, 2007; Mendoza-Denton & Worrell, [Chapter 28](#), this volume). When one set of “behavioral signatures” or *constellations* of behavior characterizes many people within one culture but not another, it can then be helpful to think about culture \times person \times situation interactions.

An example from A. Leung and Cohen (2011) shows the importance of individual differences (in endorsement of violence or endorsement of principles of inherent human dignity), cultural differences in the meaning of those individual differences (e.g., endorsing violence implies one thing in a culture of honor and quite another in a non-honor culture), and situational factors that call forth different types of behaviors (e.g., by making honor salient or by making helping a matter of reciprocity—thus making it a duty in an honor culture rather than simply a nice option).

On the one hand, the three-way culture \times person \times situation interaction can demand more statistical power and introduce unnecessary complexity. On the other hand, the design can increase interpretability of the phenomenon and, if there are large crossover interactions, can *increase* statistical power.¹ Such designs may also be *necessary* if one needs the right type of person in the right type of situation to produce the effect (see also H. Kim et al., 2010; H. Kim & Lawrie, [Chapter 10](#), this volume; Kitayama, King,

Hsu, Liberzon, & Yoon, 2016; Schroeder, Nettle, & McElreath, 2015). In these cases, culture researchers who take an individual-difference perspective but neglect the importance of situations or those who take a social-psychological perspective but neglect individual differences (collapsing together people who endorse and people who reject a cultural syndrome) may miss their effect.

Methods and Approaches

Theory and methods are closely bound for the simple reason that what we measure or manipulate in our studies will drive (and be driven by) where we locate culture's causal forces. Social-cognitive, individual-difference, and situational approaches locate culture's causal force in different places. Furthermore, many of these approaches are premised on a single cultural logic that animates behavior the same way across cultures. Analytic approaches that stress interactions, however, allow for different cultural logics to be operating in different cultures, as situations, individual differences, and primes mean something different for people in different cultures.

In summary, our methodologies and analytic approaches generally flow from our theoretical understandings of culture. And a researcher who unthinkingly adopts a certain design will usually be implicitly adopting a certain view of culture as well.

The question is not which approaches and methods are better as a default, but when each should be used. All researchers likely acknowledge the benefits each approach brings. In designing studies, we simply need to think about an issue from different approaches, make our best guess as to what causal forces are supplying the most push, consider which approach would add most to data we already have, then weigh our options and proceed.

Macro Questions: Distal Ecological, Economic, or Historical Causes

Issues of causality also arises when we ask distal questions about why the cultures we study are different in the first place. What ecological, economic, or historical factors gave rise to the cultural patterns?

For example, Nisbett (2004) and colleagues (Masuda et al., [Chapter 8](#), and Talhelm & Oishi, [Chapter 4](#), this volume) argued that a holistic thinking style developed in the East in an environment and ecology that gave rise to large-scale agriculture, an endeavor requiring cooperation and interdependence. This social interdependence in turn gave rise to a holistic way of thinking, in which context and relationships took priority over individual objects and categories. In contrast, they theorized that an analytic thinking style arose in the West because the ecology of classical Greece encouraged herding and fishing, which are more conducive to individualism than is large-scale agriculture. The individualism and atomism of Greek society in turn led to an analytic mode of thought that concentrated on focal objects rather than relationships. Furthermore, Greece's place at the crossroads of the Mediterranean meant there was a diverse "marketplace of ideas" and a need for formal systems of logic to sort out good from bad ideas.

Such views—about social interdependence leading to more holistic thinking in Eastern (vs. Western) civilizations—are given greater plausibility by two sorts of studies: (1) close comparison studies and (2) laboratory experiments that set up these causal arguments in microcosm. As noted, any two cultures will differ on a large number of variables. Using cultures that are close comparisons (see also "[minimal difference sampling](#)" later in this chapter) does not eliminate this problem, but it does reduce it. Thus, the argument that agriculture (vs. herding) leads to a more holistic thinking style was reinforced when Uskul, Kityama, and Nisbett (2008) demonstrated this effect, comparing neighboring villages in Turkey's Black Sea region that were either primarily farming or primarily herding. The argument that the need for coordination and cooperation is the key ingredient for agriculturalists was reinforced when Talhelm and colleagues (2014; Talhelm & Oishi, [Chapter 4](#), this volume) compared wheat farming versus rice farming regions in China. Maintaining rice paddies requires more cooperation and coordination than does wheat farming; and consistent with hypotheses, people in rice-farming regions had a more holistic thinking style than nearby counterparts from wheat-farming areas. Such close

comparisons—between neighboring villages rather than civilizations—reduce, but do not eliminate, potential confounds. And whereas establishing an effect at the level of communities does not necessarily mean that the same effect operated at the level of civilizations, it does enhance the plausibility of the general argument (see also Figueredo, Tal, McNeil, & Guillén, 2004; Grosjean, 2014).

Causal arguments about social interdependence leading to more holistic thinking are also supported by lab experiments that manipulate variables. In this case, such experiments showed that priming collectivism or priming individualism leads to more context-dependent (holistic) or context-independent (analytic) ways of thinking, respectively (e.g., Oyserman, Sorensen, Reber, & Chen, 2009). Again, these experiments make the causal argument more plausible, but one still has to make the leap that the causal mechanism identified in the lab was the causal mechanism that created differences out in the world. (To see the problems with this leap, note a simple example: Giving people testosterone in the lab will make them more aggressive, but this does not mean that differences in testosterone explain differences in violence rates between the United States and Canada). Lab experiments can only suggest the *plausibility* of a mechanism operating out in the world; they cannot establish that the mechanism was what actually created the real-world difference. To make stronger statements about links between ecology, economy, history, and culture, it is necessary to find data on the actual ecological, economic, or historic circumstances themselves and attempt to piece the evidence together with data that suggest causality.

Functional Explanations: Ecology, Economy, and History

In searching for distal causes, we can search for probabilistic facts (e.g., countries with access to waterways develop faster economically than those that are landlocked). However, one must remember that societies develop in a path-dependent fashion, and their histories may guide them toward one cultural equilibrium or another.

Some of these cultural equilibriums may produce “better” overall outcomes than others. And this brings us to one of cultural psychology’s implicit assumptions: namely, that cultural patterns are functional

adaptations. This is a decent starting assumption—but it is an assumption. Edgerton (1992) in particular has challenged what he calls “the myth of cultural adaptation.” Cultural practices are rarely optimal—path dependence (history) may have led to practices that were “good enough,” whereupon improvement stopped (Ridley, 2011). More importantly, cultures are occasionally quite dysfunctional (“good enough” may actually not be very good), and they are often unequal in the benefits they confer on different members of society (“good enough” for whom?). Cultural practices need not imply net collective benefit, and they may not reflect collective approval as much as collective acquiescence (Popovic, 2015; Sharp, 2013). The long history of human culture reflects greed, xenophobia, sexism, shortsightedness, irrationality, spite, and superstition as much as it reflects the better—and wiser—angels of our nature (see also Acemoglu & Robinson, 2012). As much as possible, it makes sense to attempt to verify our general assumptions about adaptiveness, being precise about what *adaptive* means and for whom (D. Cohen et al., 2018; D. Cohen et al., in press).

Aside from observations that people can be foolish and greedy, assumptions that a cultural pattern is “functional” may be problematic in another way. Contemporary cultural patterns are not necessarily adapted to *current* circumstances. A pattern that was once functional may persist well past the point of being beneficial. Thus, an honor culture may have arisen in the frontier South and West, but it may continue long after the frontier has disappeared (A. Leung & Cohen, 2011; D. Cohen et al., 2018). Gender roles, female labor force participation, and fertility patterns that developed because agricultural cultivation was done with plows (and hence required upper body strength, favoring men) or was done with hoes (and did not require such strength) persist into postagricultural societies (Alesina, Giuliano, & Nunn, 2011, 2013). And so on. Just as biological adaptations (e.g., a taste for fat and sugar) are no longer “adaptive” in places such as the United States., where people are surrounded by fat and sugar, so too are some cultural adaptations (Rozin, Ruby, & Cohen, [Chapter 17](#), this volume). A methodology that searches for contemporary reasons why a cultural pattern is adaptive may come up empty-handed or worse—it may come up with a fallacious “just-so” story for the current behavior.

Cultural psychologists have a more difficult time than do evolutionary psychologists, because genes change only slowly and cultures can change rapidly (see Mesoudi, [Chapter 5](#), this volume; Newson, Richerson, & Boyd, 2007). Thus, one can create many “just-so” stories about why a cultural pattern might be adaptive, because there is little to constrain our theorizing about *when*, *why*, and *in what circumstances* a cultural adaptation might have arisen. Functionalist explanations are seductive and often a good place to start, but they can turn fanciful when assumed rather than examined and (ideally) tested with data.

Summary

Not all cultural psychologists (particularly those doing the important basic work of description) need to worry about causality. But those who do need to think in terms of multiple equilibria, in addition to straight correlational thinking. Multiple ways of ordering the world may be meaningful, sensible, and coherent; discovering what these different cultural logics are is part of what cultural psychologists do.

Cultural psychologists also need to grapple with the question of where to begin: Social-cognitive, individual-difference, situational, and cultural logics or CuPS interactionist approaches all have something to contribute. Those doing more macro work also need to grapple with piecing together ecological, economic, and historical evidence with data suggesting causality to produce convincing arguments that go beyond just-so stories.

SAMPLING

In the causation section I described how the sampling of cultures can drive conclusions about what cultural syndromes gives rise to what patterns in particular domains. In this section I concentrate not on deciding which cultures to sample, but on how to select participants once one has decided on the populations. As seen below, approaches to sampling implicitly have views of culture built into them.

There are issues to consider in thinking about sampling. What population are we hoping to generalize to, and what sorts of hypotheses are we trying to test? I first mention the relatively straightforward case of probability sampling, then deal with the more common case of studies not using probability sampling. I end by discussing the potential opportunities that the “replication crisis” throughout the sciences represents for cross-cultural researchers.

Probability Sampling

In some cases, the leap from sample to population can be made reasonably confidently—cases in which probability sampling is used and nonresponse rates are at an acceptably low level. From the populations, one develops a sampling frame (a list of all possible elements that might be included in the study). From the sampling frame, one then draws the sample. Under probability sampling, (theoretically) all population elements have a known and nonzero chance of being selected. As noted later, generalizing from *any* sample to a population always involves some level of judgment and broader knowledge, but for practical purposes, probability sampling provides a clear scope for generalization.

Studies using probability samples are often done by sociologists or political scientists, and many are archived and available for secondary analysis. Psychologists going through survey archives may find that a typical survey does not cover a topic at the depths to which they are accustomed. However, the potential benefits of being able to find such data and use it in conjunction with data from a convenience sample are substantial. Merely having a large N gathered from a convenience sample does not give generalizability; only a probability sample can do that. (This lesson was learned by the *Literary Digest* in the U.S. election of 1936. In a spectacularly wrong forecast, the *Literary Digest* confidently predicted Landon would beat Roosevelt after getting 2.4 million respondents from across the country. Among other problems, however, the *Literary Digest* constructed its sampling frame from sources such as telephone books, car registrations, and country club membership lists. In 1936, during the Great Depression, this was a particularly rarified subset of the population).

Good sources of survey data may be found at the Inter-University Consortium for Political and Social Research website (www.icpsr.umich.edu), which houses data from sources such as World Values Surveys, the General Social Survey (and its international counterparts), and American National Election Studies. Surveys such as these have a large N in any given year, and some questions are repeated over time. With such a large N , it is possible to investigate subcultures or systematic within-culture variation by socioeconomic status (SES), region, ethnicity, and so on; also, assuming one can aggregate across years, one can get a meaningful size N for small groups that do not show up in sufficient numbers in a single year. Repetition of questions also allows for tracking changes over time, separating generation effects from age effects, and, if the study is a panel study, following the same people over time.

Nonprobability Sampling: Level of Generalization, Useful Approaches, Culture or Confound?

For most cultural psychologists, secondary analysis of survey data will be only a complement to their main work. In the section on causation, the unsolvable problem was that no correlational study can prove causation. In the sampling section, the unsolvable problem is that no study without probability sampling can generate a safe generalization, because no one knows who exactly the study's sample represents. Again, this holds regardless of study N .

Self-selecting Internet samples can have mammoth numbers of participants and get extremely precise estimates of effect sizes, but so did the 1936 *Literary Digest* poll of 2.4 million people. Such studies effectively solve the “easy” problem of precisely characterizing the sample they have drawn, but they do not solve the bigger, “hard” problem of figuring out who the results might generalize to and whether results would look different if a different sampling method were used.

Generalization is an inherent part of our work, however. How then do we deal with the unsolvable problem? Our sampling approaches are designed to be *suggestive* of some types of generalization, and a few

imperfect approaches to sampling are described later as a way to make studies more rather than less suggestive.

From Sample to Population and Vice Versa

In most noncultural psychology studies, the population is usually implicitly hypothesized to be all human beings, the sampling frame is the list of sophomores in Psychology 100 this year, and the sample is the 80% of those selected who show up to participate in our study. As Henrich, Heine, & Norenzayan (2010) have pointed out, most claims about “human nature” are actually based on WEIRD (Western, Educated, Industrialized, Rich, and Democratic) samples.

In most culture studies, the population-to-sample link is only slightly better. The population might implicitly be something like the 2.5 billion members of Eastern civilization and the billion members of Western civilization. The sampling frame is the Asian Americans and European Americans in Psychology 100, and the sample is those who show up. The absurdity of going “too big” in one’s generalizations is obvious here (see also Rentfrow & Jokela, [Chapter 29](#), this volume).

Consider also the opposite problem of going “too small” and the paralysis it leads to in selecting a sample or drawing conclusions. A researcher considers a study comparing the political cultures of Brazil and Argentina with the United States and Canada. The researcher wants to argue that some result illustrates a difference between political cultures of Latin American and North American societies. A critic would correctly point out that Latin America is not “monolithic.” South American countries are different than Central American countries. And within South America, Brazil and Argentina will be different from, say, Peru and Bolivia. Within Brazil, states of northern Brazil will be much different than those of southern Brazil. And within southern Brazil, the state of São Paulo will be different from, say, the state of Santa Catarina. And within São Paulo state, the city of São Paulo will be different from those further inland. And within the city of São Paulo . . . and the regression can go on ad infinitum, until one is thoroughly torn about where to start the research and afraid to make any

homogenizing statement or generalize past the N specific subjects in the study once completed.

For anyone not using a probability sample, the generalization problem is always there, whether acknowledged or not. For example, a researcher studying, say, parent–child socialization might sensibly say that he or she does not care if the results generalize to other Asian populations or to all Japanese. He or she may situate the research as examining processes within upper-middle-class Japanese and American parent–child interactions; that is, the researcher may argue that the work concerns not the “grand” traditions (Eastern vs. Western culture, Buddhism, Confucianism, etc.) but “local” traditions (see also Glazer, 2000). However, without probability sampling, the researcher has no reason to believe that the findings of the sample apply to other upper-middle-class Japanese and American parents, to other upper-middle-class Japanese and American parents from these particular towns, or these particular neighborhoods, and so on.

If one wants to talk about findings as applicable to groups other than the specific subjects in the study, a generalization is being made. More importantly, if one wants to talk about something as “cultural,” then one is definitionally talking about something shared among a group of people usually larger than the particular set of participants in one study.

Leaps in overgeneralizing are relatively easy to catch. But in prestudy planning and poststudy interpretation (see later discussion in the chapter), thinking about and making generalizations that are too small and too context-specific has its own risks. One of those risks is that one’s explanations for phenomena become too parochial. One may explain phenomena in terms of reasons that might actually be superfluous. For example, researchers aiming to be appropriately contextual and avoid sweeping pronouncements might focus their work on, say, the drop in violence in New York City since the 1990s, the greater religiosity of Catholic women versus Catholic men, or the declining fertility rates among Jewish women. But anyone wanting to comprehend these phenomena should know that crime dropped in almost all of the developed world around that time, that women tend to be more religious than men in most religions, and that fertility rates all over the globe have been falling for decades. A researcher who focuses too narrowly on his or her sample—*overlocalizing* or *overcontextualizing*—and does not think about making connections to some

larger population runs the risk of missing the big picture. This does not justify making grand pronouncements from limited data. It is just to say that one's research setting is located within a larger setting, one's phenomenon likely exist within a larger class of phenomena, and it is easy to miss the larger forces that buffet our local worlds. An appropriate level of generalization from nonprobability samples—and even from probability samples—requires some broader knowledge and judgment, so that one can negotiate between the hazards of overgeneralizing and overlocalizing.

Sampling Approaches and Purposes

Acknowledging the subjective judgments involved in making generalizations from *any* sample and the unsolvable problem of using *nonprobability* samples, there are at least four approaches that still may help us say something useful about culture and how it works: the *typicality approach*, the *just minimal difference approach*, the *cultural experts approach*, and the *inversion approach*. Each may be useful for a different purpose. They are all, of course, imperfect.

The Typicality Approach versus the Just Minimal Difference Approach

A researcher is comparing cultures *A* and *B*. How should the researcher draw samples of people or schools (or whatever the sampling unit is) from groups *A* and *B*? One principle is to match on “typicality,” so that one might compare “typical” groups in culture *A* with typical groups in culture *B* rather than having to compare typical groups in culture *A* with outlier groups in culture *B*. A competing way might be to match participants from the two cultures on the principle of the “just minimal difference.” In the latter approach, one tries to match the samples as closely as possible on all variables, so that the “only” difference left is the difference in the cultural histories of the two groups. Practically speaking, the samples are made as similar as one can reasonably make them, so that exposure to culture *A*

versus exposure to culture *B* becomes the *most obvious* explanation when other obvious but “noncultural” factors have been equated.

The difficulty in the first approach is clear. How does one decide who is “typical”? It is far easier to decide who is *atypical* than to decide who is typical. For example, it is safe to say that a sample from Beverly Hills or northern Idaho may not be a “typical” U.S. sample. But who qualifies as typical? In saying a group is “typical,” researchers usually mean *not atypical* in many obvious ways. Unless there is some well-established modal group that is statistically quite common or some culturally agreed-upon prototype, it is likely that judgments about who is *typical* or not atypical are going to be a subjective call.

The latter approach—the just minimal difference—has an intuitive appeal to psychologists who primarily use controlled experiments. It attempts to mimic random assignment by keeping “everything else constant” and just concentrating on the cultural difference of interest. The problem is that there is no real random assignment, so there is no “everything else constant.” However, there is also a more theoretical problem: This approach implies that one is able to sort out what is the “cultural” factor from what is a confound or an extraneous factor. It is not clear that this is possible or even always desirable (see also Medin, Unsworth, & Hirschfeld, 2007).

One probably does not want to consider *all* differences between two cultural groups as a *cultural* difference (as opposed to an economic difference, ecological difference, demographic difference, etc.; e.g., W. Wilson, 2010).² However, depending on the area of study, the line between what is cultural and what is, say, a confounding demographic factor can get quite blurry. For example, what does it mean to control for income when comparing cultural groups that renounce worldly success versus those that embrace it as a sign of the elect? Or what does it mean to control for education in comparing groups that emphasize formal schooling versus those that do not? (See Glazer [2000, p. 226] also for similar discussions of preference for rural vs. urban living, or family size and structure as both a demographic variable and a “cultural feature par excellence,” etc.). As Adams and Markus (2004; also see Markus & Hamedani, [Chapter 1](#), this volume) noted, one essential part of the “dynamic construction” approach to culture involves the blurring of the division between what is “culture” and what is “social structure,” because both re-create each other. Some of the “everything

else” that one is trying to get rid of may be a defining part of the cultural phenomena.

Then again, maybe not. Thinking about these issues forces a researcher to think about the nature of his or her study: (1) Is the aim to focus narrowly and analytically on a specific, circumscribed cultural practice, so that one can pinpoint its importance? (2) Is it to identify this difference as more “cultural,” implying that it expresses some sort of chosen value for the group that will endure even if more “structural” or demographic changes occur? If either (1) or (2) is the goal, that might favor sampling based on the “just minimal difference” approach, so that one can focus on the practice of interest, keeping at least *some* “other things equal.” Or, for example, is the aim (3) to capture the “Gestalt” of the culture—to examine how various aspects of the culture fit together and support one another (or clash)? If so, that might suggest a sample based on some definition of “typicality,” in which it does not make sense to “keep all else equal,” because “all else” is part of what one is trying to study.

In some ways, the answer to the question of whether one wants to focus analytically or to capture a Gestalt is like the answer to whether one wants vanilla or chocolate ice cream. The correct answer is, “Yes, both.” In that case, within a given study, one can sample not only widely but also strategically, selecting some of the sampling units based on the principle of “typicality,” and others based on the principle of “just minimal difference.” For example, if one is drawing a sample of, say, 10 schools, one can choose, say, five “typical” schools from each culture, then choose the other five schools with an eye toward matching them as closely as possible, so one can isolate a particular characteristic of interest. Research budgets often do not allow for such sampling and, in that case, one has to determine the most important goals for the study.

Expert Sampling versus Inversion Sampling

Expert sampling and inversion sampling represent two opposite approaches. One stacks the deck in favor of finding the cultural difference; the other stacks the deck against it. In *expert sampling*, one makes no pretense of studying the average group member. Instead, one tries to bring cultural

systems into sharp relief by studying cultural “experts,” where “experts” does not mean scholars but rather the people most immersed in, most competent in, or who most embody a culture in its more “pure” form. A study with cultural experts may stand on its own, or it may be a prelude to future studies involving wider populations. For example, in studying reasoning about the natural world, Lopez, Atran, Coley, Medin, and Smith (1997) focused on Itzá Maya elders who spoke Itzá—clearly an exceptional group, because “the ‘typical’ Itzá speaks mainly Spanish” (Medin & Atran, 2004, p. 964). Then, once sharp cultural differences have been defined through studies that use expert sampling, subsequent research might study the distribution and transmission of these “expert” ideas across networks within the community. The appeal of expert sampling is obvious and is consistent with Kurt Lewin’s directive to “start strong.” However, drawbacks are also obvious: (1) It will not always be clear who the “experts” are, or who is most culturally competent (again, it is probably easier to identify who is not an expert) and (2) depending on the size of the gulf between the experts and everybody else, findings on the expert population may or may not prove useful in generating subsequent research with nonexpert populations.

A different possibility is to do the opposite of expert sampling and sample the subgroups that theoretically would be *least* likely to produce a cultural difference. There are a few reasons one might do this *inversion sampling*. For example, one might want to strengthen the generalization inference by showing that the cultural difference exists even in extreme cases when the cards are stacked against it. Thus, in studying political culture, if one showed that even the most conservative Canadian province favored socialized medicine more than the most liberal U.S. state, one can make a stronger inference about a more general U.S.–Canadian difference. A very different reason to engage in inversion sampling might be to test one’s understanding of a phenomenon by “flipping it on its head,” as Norbert Schwarz would say. Suppose, for example, one were studying differences in fatalism between country *A*, which primarily grows a high volatility commodity *a*, and country *B*, which primarily grows relatively stable commodity *b*. If one wanted to focus on the connection between commodity volatility and fatalism, it might be useful to include in one’s sample some unusual regions from country *A* that grew commodity *b*, and some unusual regions from country *B* that grew commodity *a*.³ In the typical regions of

countries *A* and *B*, one might show how *A*'s practices are more fatalistic than *B*'s; but with the atypical regions, one might strengthen the causal argument about volatility and fatalism by showing that the effect flips on its head in these atypical regions. This type of sampling has an appeal to experimentally trained cultural psychologists. However, the same limits about claiming causality still apply, because the independent variable (in this case, commodity volatility) was still measured rather than manipulated (see also Kitayama, Ishii, Imada, & Takemura, 2006).

College Student, Mechanical Turk, and Ethnic Group Sampling

Issues in sampling college students, Mechanical Turk (MTurk) workers, and ethnic groups are just special cases of the general issues discussed earlier. Nevertheless, they merit greater treatment, because practical considerations (ease of recruitment, ease of standardizing procedures, etc.) make using such samples quite popular.

College Student Samples

Given a desire to create the just minimal difference and the convenience of college samples, many researchers opt (1) to find comparable colleges, then sample college students from various countries or (2) to study college students of different ethnic groups within a single country (see below for more on the latter). In psychology as a whole, around 80% of research on “normal” adults has used such college student samples (Rosnow & Rosenthal, 2002; also Arnett, 2008; Belot, Duch, & Miller, 2015). Within cultural psychology, no one has yet calculated a comparable estimate.

There are the usual hazards of using college student samples, then hoping to generalize beyond them. However, for those working in more than one culture, there are additional concerns. Within the United States, we know some of the ways college students differ from the wider population (see Sears, 1986), but such data may or may not be known for other countries (Hanel & Vione, 2016). Furthermore, outside the developed world,

college students are likely an even more rarefied section of the population than they are in the United States. A researcher trying to create the just minimal difference may wind up comparing a college student elite in the developed world with a college student superelite elsewhere. The researcher may be equating on formal education, but he or she is not equating on social status or life chances. Whether there is an education effect or a social status effect—and which one it might be more important to equate on—will likely depend on the research topic.

Many people's intuitions are that comparing, say, a U.S. elite with a non-U.S. superelite lessens the chance of finding cultural differences, because "cosmopolitan elites" share certain traits and values across the world (Shweder, 2000; see also Hitoko, Glazer, & Kitayama, 2016; Kraus, Callahan, & Ondish, [Chapter 27](#), this volume). For researchers hoping to find a cultural difference, this is a good thing, because it means the confounding factor usually works *against* the hypothesis and it is therefore not a plausible alternative explanation if differences are found. However, in any given case, it is an empirical question whether cosmopolitan elites will be more like each other than are their respective populations, and we may or may not have the data to settle it for every particular domain or group.

MTurk Samples

Use of samples from Amazon Mechanical Turk (MTurk) and similar "crowdsourcing" websites helpfully expands the population past college students. However, the same conceptual problem of different self-selection processes operating in different cultures remains. What brings a person to MTurk from culture *A* may not be what brings a person to MTurk from culture *B*. Understanding how they are different can be a bit difficult, because the pool is constantly shifting (Ross, Irani, Silberman, Zaldivar, & Tomlinson, 2010; Stewart et al., 2015). However, previous studies have identified a few trends. The vast majority of MTurk workers are from the United States and India, and, not surprisingly, they come to the task with different motivations and backgrounds. Thus, a straight comparison between MTurkers from India and the United States compares mostly well-educated U.S. women taking surveys for fun and pocket money with

hypereducated Indian males (75% have at least a bachelor's degree), a substantial portion of whom do the experiment as work to produce their primary source of income (Ipierotis, 2010). One can, of course, try to equate on these variables by prescreening or statistically controlling for them, but it is an open question as to what other variables one is not controlling for.

Within-country comparisons likely reduce this problem for some groups, but there still seems to be a selective pull, with African American and Hispanic Mturk workers being only about one-third or one-half what they are in the U.S. population at large (Berinsky, Huber, & Lenz, 2011; Christensen & Glick, 2013; Huff & Tingley, 2015). Mturk workers are an unusual slice of the population, but they may be more unusual representatives of some populations than others.

Comparisons between Ethnic Groups and between Countries

To create the “just minimal difference,” some studies examine ethnic groups within a country as opposed to between countries. For example, one might study Chinese Americans and European Americans rather than people in China and the United States. There is much to be said for this, and, very practically, keeping the study at one location also helps equate the operational details of actually running the study. For example, if one is running a study examining how European Americans and Chinese Americans respond to a loss of face, one can employ the same face-losing procedure with the same experimental confederates. And even when the study is not a high-impact (highly involving) lab experiment, a study involving European Americans and Chinese Americans can use an English questionnaire to avoid translation ambiguities (discussed in the “[Operationalization](#)” section) or extraneous effects of language (Chiu, Leung, & Kwan, 2007; Loewenstein, [Chapter 9](#), this volume; Perunovic, Ross, & Wilson, 2005; Wang & Ross, 2007), if such effects are indeed extraneous.

However, if one wants to talk about Chinese culture and American culture, comparing European Americans with Chinese Americans minimizes some difficulties but creates others. For one thing, if one is using

recent immigrants or even sojourners here to go to college, a whole set of challenges accompanies trying to settle into a new culture (Mesquita, De Leersnyder, & Jasini, [Chapter 19](#), and Morris, Fincher, & Savani, [Chapter 18](#), this volume). Also, even if one does not use recent immigrants, culture will be confounded with majority or minority status in most places in the United States. And as another matter, immigrants and sojourners are likely to be systematically different from their counterparts back home on at least some personality and demographic variables. For example, sojourners who have left their homes and families to study in another country may be more individualistic than their counterparts who chose to stay (e.g., Hitokoto et al., 2016). In some cases, this is fine, because some preexisting differences and some challenges that immigrants face may work against one's hypothesis and so cannot be alternative explanations. However, in other cases, it will not always be clear that this is so. Thus, generalizing from Chinese Americans to Chinese culture or generalizing from Chinese culture to Chinese Americans is not a move that can be taken for granted (Glazer, 2000). Again, more abstractly, it may not be simple to go from the "local" traditions of a particular group in a particular place to the "grand" tradition (e.g., Eastern culture) from which it may have derived (and vice versa for the direction of inference).

A Novel Sample: Culture as an Experimentally Primed Variable

Samplings based on typicality, just minimal differences, expertise, and inversion are four of the multiple ways one might choose to sample. The just minimal difference approach and inversion approach likely appeal to experimentally trained psychologists. However, the fundamental problem is that we cannot get rid of third-variable problems, because we cannot randomly assign people to a culture and consider it a manipulated variable.

There has been at least one ingenious sampling strategy for helping with this problem, though. Hong, Morris, Chiu, and Benet-Martinez (2000; A. Leung & Koh, [Chapter 21](#), this volume) have done studies in which the sample is made up of bicultural individuals who have been socialized in two cultural traditions (e.g., Asian Americans or residents of Hong Kong). These

bicultural individuals are then randomly assigned to receive an experimental manipulation priming them with either Chinese icons (the Great Wall, a Chinese dragon) or American icons (Marilyn Monroe, the American flag). In their research, Hong et al. have, for example, shown that Chinese icons tend to push bicultural individuals toward Eastern, group-centered descriptions of events, whereas American icons tend to push them toward Western, individualistic descriptions. One does not get around the problem that bicultural individuals are a special subset of the population, but one does reduce the problem of confounding culture with some of the other variables one would like to control. According to one way of thinking, bicultural individuals were a problem to be avoided—they were too tainted by culture *A* to be a “true” member of culture *B*, and vice versa. Hong et al.’s important move was to see working with such individuals as an opportunity to manipulate (at least temporarily) cultural schemas. These manipulations make certain cultural knowledge structures more salient through the presentation of icons, the language in which the study is run, or the (real or imagined) audience for one’s behavior. All sampling techniques are flawed in some way, but as cultural psychology matures, it will help if more of these clever sampling techniques are developed as part of the discipline’s repertoire.

An Opportunity?: The Replication Crisis

In the preceding sections I have discussed how, as primary researchers, we might choose to sample. But sometimes opportunities fall in our lap. One may arise with the “replication crisis” that has hit the sciences, including all the quantitative social sciences, as well as medicine, genetics, and so on. The failures to replicate are certainly a cause for concern. They are an impetus to seek improvement. However, they also represent another opportunity for psychologists interested in culture.

Some failures to replicate result from random error, producing false positives in the original study or false negatives in the replication. Some result from questionable practices. However, some likely result from cultural variation. Van Bavel, Mende-Siedlecki, Brady, and Reinero (2016; Inbar, 2016; also Gilbert, King, Pettigrew, & Wilson, 2016), for example, found that

one of the best predictors of whether a psychology study replicated was whether the research topic was “context sensitive” (defined as likely to vary by “time, culture, or location”; Van Bavel et al., p. 6454). In economics, Nobel Prize winner Angus Deaton has expressed similar skepticism about whether interventions designed by development economists will translate from one setting to the next (see Cohen, Shin, & Liu, [Chapter 22](#), this volume). And indeed, it is not surprising to find conflicting studies in this domain as well. Sometimes the reasons are relatively prosaic (e.g., a failure to follow procedures closely; Karlan & Appel, 2016).⁴ Other times, conflicting results may arise from more substantive cultural differences (some interventions may not work where generalized trust is low, where women are not sufficiently empowered, where tight cultural norms prohibit deviation from tradition, where concerns for hierarchy or purity are more important than efficiency, etc.). There are reasons why people may not always choose to do what is “rational,” efficient, or economically savvy. Some are small. Others are big (or as Ayatollah Ruhollah Khomeini once apocryphally remarked: “The people did not make the Islamic Revolution to lower the price of watermelons”; see also Oyserman, 2015; Oyserman, Fryberg, & Yoder, 2007). It is possible we can learn something about culture, mechanisms of persistence and change, and conditions that make markets work or not from such research.

Most of the time we aim for robustness. However, cultural psychology as a field is what Taleb (2012) called “antifragile”—it is a field that can potentially *gain* from variability, shocks, and “disorder.” That is because what is “error” for most disciplines—and most parts of psychology—is actually a topic of study for us. One opportunity for cultural psychologists is to help explain why effects or interventions that hold in one place do not work or even reverse in another. The key will be to actually *measure* the variables that moderate an effect’s generalizability, then, if at all possible, take what we have learned from one analysis and examine it in other settings, with other datasets, other populations and measures, and ideally, conduct a study that allows us to *manipulate* the variable of interest. This is potentially a great opportunity for cultural psychologists, but to exploit it, we have to be able to say more than just “It’s culturally variable” or tell a “just-so” story. We need to convince people in our own fields and others that what appears to be

“sampling error” is actually systematic *measurable* or *manipulable* cultural variation that is substantively interesting.

Currently, places cataloguing replications are relatively limited. Websites include Open Science in psychology (<https://osf.io>); Social Science Registry (socialscienceregistry.org) and development economics sites (e.g., povertyactionlab.org and poverty-action.org); Cochrane Library (cochranelibrary.com) for health interventions and other controlled trials; Dryad (datadryad.org) for evolutionary biology and ecology; Harvard Dataverse across various fields (dataverse.harvard.edu); and various journals. More will likely follow.

Sampling Technique(s) Appropriate to the Research Question

In summary, cultural psychologists need to take the issue of participant sampling seriously; that is the basis for the field’s critique of mainstream psychology as a psychology of relatively elite Western populations. Rarely do cultural psychologists use probability sampling themselves, so it is definitionally unclear to whom our results generalize and at what level to contextualize and hence, to understand them. Yet, in our own studies, various sampling techniques may help us say something useful about culture and how it works (e.g., typicality sampling vs. just minimal difference sampling, expert sampling vs. inversion sampling, bicultural sampling).

There are trade-offs in choosing one type of sample or another. Different sampling techniques have implicitly built into them different views of what culture is. For example, as described earlier, issues of whether one is dealing with the grand traditions or local ones, of how best to keep “everything else equal,” of what is culture and what is confound are questions implicit in how the samples are selected. To make good decisions as researchers and good interpretations as readers, we need to define research questions precisely, think through the sampling trade-offs we might make, and choose the sampling technique(s) most appropriate for our project. Analyses of archived studies rarely let us choose our own ideal samples, yet they may act as complements and springboards for studies we ourselves conduct and about which we make thoughtful sampling decisions.

OPERATIONALIZATION

Once one has thought through issues discussed in previous sections, one needs to operationalize the hypothesis with measures of the dependent variable and measures or manipulations of the independent variable. Several excellent guides explore the art and science of operationalization (Berry, Poortinga, & Pandey, 1996; Ellsworth & Gonzalez, 2003; T. Wilson, Aronson, & Carlsmith, 2010), design, statistical power, and cost (Lakens, 2014; McClelland, 1997), questionnaires and surveys (Groves et al., 2009; Schwarz, 1999). This chapter only briefly sketches out a few issues as they apply to culture. For all social scientists, the essential challenge of operationalization is to create variables that are convincing and interpretable. For cultural psychologists, these variables have to be convincing and interpretable when seen through (at least) two different cultural lenses.

Translating Languages, Translating Situations

One of the big issues for cultural psychologists is that of “translation,” which is loosely defined as making sure one’s measures and manipulations are the same across cultures. The issue is obvious when it comes to language, but it also applies to translating situations and observations, as discussed later (see also Fiske, 2002; Kashima, 2014; Oyserman & Yan, [Chapter 20](#), this volume).

Linguistic Translation

If the study is to be conducted in two or more languages, one must have materials translated and backtranslated. Thus, a first bilingual translates materials from Vietnamese to Russian, and a second bilingual translates the materials back from Russian to Vietnamese. One can also add a number of different protections, including having multiple teams of bilinguals do the translation, backtranslation, and reconciling of differences.

Careful execution of this process is tedious—and completely necessary. Even the very best surveys struggle with translation issues—sometimes words differ in connotations across contexts (Davidov, Meuleman, Cieciuch,

Schmidt, & Billiet, 2014; K. Leung & van de Vijver, 2008; Mellon, 2011). Other times there are simple errors. Examining data from the World Values Survey, Kurzman (2014), for example, believes it likely that differences in translation accounted for why 99% of Vietnamese surveyed supported military rule in 2001, but only roughly 33% did so a few years later, as well as why similarly dramatic changes were seen in Iran and Albania. If even the World Values Survey, generally regarded as the “gold standard,” can have such issues, errors and idiosyncratic judgments likely occur in projects done with far less expertise. Thus, whereas some questions are probably robust to various wordings, others are not; and it pays to show considerable care in the translation process.

Translations, Quantifiers, and Reference Group Effects

Even within English, there may be translation issues from region to region. For example, if the word *argument* is taken to mean any sort of disagreement that involves raised eyebrows in subculture *A*, whereas it means a shouting match that would drown out a rock concert in subculture *B*, one might find that the frequency of “arguments” in *A* is startlingly high compared to that in *B*. In this case, ambiguity in the meaning of the word *argument* adds not only noise but also bias.

These differing definitions and standards can arise partly out of reference group effects (Heine, Lehman, Peng, & Greenholtz, 2002). So, for example, when a Korean or American respondent is asked whether he or she “respects authority,” the respondent needs to figure out what “respecting authority” means, and figure out an appropriate standard for comparison—and Korean and American respondents may have very different definitions and comparison groups. Heine and colleagues argue that reference group effects explain why individualism–collectivism scales often do not show the differences one would expect between Easterners and Westerners, as well as why the Big Five measure of Conscientiousness has little predictive validity for cross-cultural comparisons (Heine, Buchtel, & Norenzayan, 2008; Lazarevic & Knezevic, 2017), though Oishi and Roth (2009) found somewhat more encouraging results. There have been various suggestions for how to deal with these problems (e.g., giving people the reference group or standard to which one wants them to compare themselves; providing

scenarios or vignettes to which people respond; asking about specific behaviors; avoiding “vague quantifiers” such as *occasionally*, *sometimes*, or *often* and instead ask for frequencies in hard numbers; having people make pairwise comparisons rather than respond to Likert-type scales; having people rank rather than rate; and so on; Harzing et al., 2009; Heine et al., 2002; Oishi et al., 2005; Peng, Nisbett, & Wong, 1997; Schwarz, 1999; Wong, Rindfleisch, & Burroughs, 2003)—but likely there is no single, foolproof technique that is best in all situations, and researchers will have to pilot-test and use their judgment.

There are other phenomena that can invert self-reports. Such is the case when a cultural syndrome creates a response bias that undercuts one’s ability to measure it. For example, Ramirez-Esparza, Gosling, and Pennebaker (2008) argue that the Latino cultural script of *simpatía*—involving being friendly, agreeable, and polite—encourages one to be modest when rating oneself on characteristics—including characteristics such as friendly, agreeable, and polite. Thus, Latinos reliably score lower on self-ratings of Agreeableness, perhaps due to *simpatía*’s concern with modest presentation. Interestingly, Ramirez-Esparza and colleagues showed that Latino bilingual participants run in Spanish (vs. English) became more *simpatico*/agreeable in their behavior, even as they rated themselves less *simpatico*/agreeable in self-reports.

Translating Situations and Behaviors

Avoiding vague wording and asking more objective behavioral questions generally lessens error and bias that occur when participants in different cultures construe questions differently. High-impact laboratory experiments that call for specific behaviors go even further toward doing so. However, one must still make sure the situations one constructs and behaviors one measures translate from one culture to the next. The bargain one strikes for the sake of clarity is this: The more one specifies particular situations, and the more narrowly one operationalizes a variable, the more likely one is implicitly pushed toward examining a phenomenon as an etic (universal) construct that is played out the same way across cultures—rather than as an emic, or more culturally specific, construct that is approached in a culture’s

own terms. Thus, the trade-off is that the more one is concrete, the less one will have error and bias about *that particular set of behaviors*; but the more one is concrete and narrow, the greater the risk of missing emic phenomena or constructing what Triandis (1994, p. 69) called “pseudoetics” (false etics).

That is, one may measure, say, intelligence (Mirsky, 2012; Nisbett, [Chapter 7](#), this volume), wisdom (Grossmann & Kung, [Chapter 13](#), this volume), secure or insecure attachment (see Keller, [Chapter 15](#), this volume; Morelli & Rothbaum, 2007), reasoning ability (Norenzayan, Choi, & Peng, 2007), social class (Cohen, Shin, Liu, Ondish, & Kraus, 2017b; D. Cohen, Shin, & Liu, 2019), self-esteem (Kitayama et al., 1997), competitiveness (Keller & Loewenstein, 2011; Loewenstein, [Chapter 9](#), this volume), religiosity (A. Cohen & Neuberg, [Chapter 32](#), this volume; A. Cohen, Hall, Koenig, & Meador, 2005), emotional expression (Tsai & Clobert, [Chapter 11](#), this volume), mental health and illness (Chentsova-Dutton & Ryder, [Chapter 14](#), this volume), love (Hatfield et al., 2007), and so on. And the more concretely and precisely one measures these constructs, the less “noise” there will be. However, precision may also mean narrowness, and the more narrowly the construct is operationalized, the more likely it is to privilege one culture’s definition of the construct over another’s.

Coding secure versus insecure behavior in the Strange Situation task or coding moral reasoning via Kohlberg’s scheme illustrates the possible problems of narrow definitions, modeled on American templates (Keller, [Chapter 15](#), and Miller, Wice, & Goyal, [Chapter 16](#), this volume; Morelli & Rothbaum, 2007). However, there are cases in which the problem is not simply coding responses to a situation; *the entire situation* itself may fail to translate—for example, when Scandinavian psychologists went to study the institution of the “family meal” in India. Their Indian contacts helpfully set up a family meal for researchers to videotape but were too polite to tell researchers that family meals did not actually exist in this village (Shweder, 1997).

Situations and behaviors—in both experiments and observational studies—can fail to “translate” across cultures. Ultimately, there is no substitute for background reading, having informants or collaborators who are familiar with the culture, pretesting measures, probing respondents for their understanding of concepts and behaviors, and using a combination of techniques—some “operant” methods that are loosely controlled,

exploratory, and driven primarily by the participant and some “respondent” methods that are more tightly controlled, well-defined, and driven by the researcher’s specific hypotheses (Triandis, 1994, p. 80; Church, 2016).

Strategies and Cost–Benefit Trade-Offs of Surveys versus Experiments

Often, researchers can operationalize their hypothesis in a naturalistic observational study, a questionnaire (open- or closed-ended), or a laboratory experiment. Again, the best answer about which to do is: all of them. However, pragmatic concerns often dictate that one is preferable or at least needs to be done first. In nonqualitative research, it often comes down to whether one begins with questionnaires or experiments. There are two schools of thought on this.

1. *Cast a wide net, but what have you caught?* According to one school, investigators need to start by casting the widest possible net to explore a phenomenon. The questionnaire (either open- or closed-ended) is far more efficient for this purpose. Not only can one run many, many participants at once, but one can ask about a wide array of situations and an extended history of behaviors. If one is studying adolescent stress, for example, in a few pages, one can ask about stressors related to home, school, work, friends, peers, romantic partners, and so on. One can ask about situations from the past and ask respondents to speculate on situations that might happen in the future. One can get answers covering a huge variety of situations.

The question, however, is how much to trust those answers. In addition to reference group effects and ironic dissociations between self-reports and behavior, there are more mundane concerns about response biases that affect any questionnaire study. What is particularly troublesome for cross-cultural researchers, however, is the possibility that cultures are differentially susceptible to different response biases. For example, people from hierarchical and uncertainty-avoidant cultures, as well as perhaps honor cultures, may be more likely to give extreme responses that use the endpoints of the scales; those from hierarchical and collectivistic cultures

may be more likely to show acquiescence bias; those from dialectical cultures may be more biased toward the midpoint (though it is not clear whether this is a “bias” or the natural result of thinking dialectically) (Hamamura, Heine, & Paulus, 2008; Harzing, 2006; Johnson, Kulesa, Cho, & Shavitt, 2005; Lalwani, Shavitt, & Johnson, 2006; Smith, 2011; Tellis & Chandrasekaran, 2010).

Some protections for some problems may be put in place (e.g., having an equal number of reverse-scored and non-reverse-scored items can lessen problems created by acquiescence bias). However, there are deeper problems with questionnaires that can be difficult to overcome. These involve problems in which participants may not be able to correctly tell us about their behavior or attitudes, *even if they want to*. Depending on the domain, people may have great difficulty identifying reasons for their actions, articulating their preferences, and predicting their future behaviors and emotions (D. Cohen, Kim, & Hudson, 2014, 2017a; Nisbett & Wilson, 1977; Gilbert & Wilson, 2007; Morris, Fincher, & Savani, [Chapter 18](#), this volume; Weinstein et al., 2012)—even when extremely important life events are involved (Pauker & Pauker, 1979).

There are some “tricks” that can be helpful. Becker (2008) advises that people have trouble answering “why” questions; so instead, ask them “how” questions. For example, “How did you come to join this *jihadi* group?” is much more easily (and less defensively) answered than a question such as “Why did you become a *jihadi*?” The “why” question calls for self-insight but is likely to be met with “party line” answers about reestablishing the caliphate. On the other hand, with enough answers about “how”—for example, with enough stories about youth leaving aimless lives after they meet *jihadi* recruiters promising glory and adventure (Atran, 2008; [Chapter 31](#), this volume)—a researcher can both deduce a theory of “why” and build an underlying narrative of process. Overall, though, the difficulty in getting accurate, informative self-reports is one reason some researchers shy away from them.

2. *Start strong. Or try to.* The second school of thought on where to begin is to follow Kurt Lewin’s advice and “start strong.” In this case, one might begin with an experiment that engages the psychological process one wants to examine (as opposed to a questionnaire asking participants to

report on such processes). Sometimes these psychological processes are purely cognitive, and the tasks engage the participant enough to bring the relevant processes online. Other times, processes are more emotional, in which case a high-impact manipulation that actually creates the emotion in the participant is extremely helpful.

Emotions transform the way we experience the world, and in a “cool” state, it is not so easy to predict how we would behave in a “hot” state (Loewenstein & Schkade, 1999). Milgram (1974) provided a classic example. There is little chance that the behavior of participants in Milgram’s high-stakes, high-pressure experiment would have been predicted by participants (or any other naive person) in a cold state filling out a questionnaire. In terms of more prosaic examples, anyone who has ever said something in anger that he or she did not mean, or has gone grocery shopping on an empty stomach, can attest to the truth that hot-state preferences and behaviors are different from, and cannot easily be predicted by, statements and behaviors made in a cold, detached state.

In an experiment, one can set up situations designed to maximally trigger the response one wants to study. Note that the trade-offs between surveys and experiments complement each other here. Surveys can ask about a wide array of situations, but in a great many cases, their pallid questions may provide underwhelming evidence about differences in any particular situation. Conversely, experiments can produce big differences in situations that have been constructed to be “just right.” However, at the start of a research program, (1) we may not yet know what is “just right” and (2) we cannot know the extent to which results from our “just right” situation generalize; for that, questionnaires asking about a variety of situations (without having to create them in the lab) may be helpful.

Fundamental Paradoxes and Essential Problems

Those with an experimental social psychology background will recognize in the description of the “just right situation” one of the fundamental paradoxes of social psychology (D. Cohen, 2015). That paradox is: We study a behavior in one setting or context, hoping to generalize to other settings and contexts. However, our entire field tells us that settings and contexts

matter tremendously; that cross-situational consistency cannot be assumed; and that seemingly small details of the situation can have dramatic impacts on behavior. Thus, the main lessons of our discipline undermine our ability to generalize from our strongest methodological paradigm—the lab experiment with all the details set up just right to maximally engage the process we want to study. If details matter so much in the lab, why would they not matter in trying to generalize results from our studies to other situations?

This fundamental paradox—that we try to generalize results from our situation to other situations when we know that generalizing across situations can be extremely hazardous—helps pinpoint the value and limitations of experiments. Their value lies in the controlled study of phenomena, allowing us to discern causes; to manipulate factors that turn processes on or off, exaggerating or reducing effects; and to measure outcomes, behaviors, emotions, and mental processes in a way that is difficult to do cleanly in the world. These are incredibly valuable, and to understand some phenomena, it is profoundly useful to bring them into the lab and study them.

It is also important to clearly see experiments' limits. For example, we can closely study behavior in the lab, but we need to remember that sometimes our situations will be contrived (Winking & Mizer, 2013). We can manipulate a variable of interest, but we need to remember that perfectly “clean” manipulations exist mostly in theory—that we are manipulating not only the conceptual variable we are interested in *but also every other variable that naturally correlates with it*. As psychologists, our comparative advantage is that we can do experiments in ways that sociologists, macroeconomists, and political scientists usually cannot. This is what we bring to the party. The lab experiment is a powerful tool, but it is not the only tool, it is imperfect, and it is only a stand-in for the real-world behavior we want to study.⁵

Neuroscientific Data

Before leaving laboratory studies, one other newer methodology deserves mention: neuroscience studies using techniques such as event-related

potentials (ERP) or functional magnetic resonance imaging (fMRI). Neuroscientific measures can be extremely useful for several reasons: (1) Like some other physiological measures, they are hard to fake, which means they are less susceptible to social desirability or other response biases; (2) they may often tap psychological processes to which participants have little access, even if they try to introspect (Kitayama & Salvador, 2017), and thus may illuminate less conscious processes, as well as tacit knowledge that participants have trouble articulating; and (3) as suggested by Kitayama and Salvador, they may effectively capture long-term socialization, providing a cleaner look at chronic response patterns, because brain responses may be less affected by situational demands than behavior is. Under the idea that “neurons that fire together, wire together,” neural networks track “cumulative cultural effects” (p. 844) of long-term learning. The networks provide a sort of “natural history” of socialization as certain pathways get etched into people’s brains over a lifetime of experience in a culture. Neuroscientific methods are new-ish, but they have already yielded positive results, capturing some cultural differences that are difficult to get at with other methods (Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume).

Cultural psychology will gain from importing neuroscience methods. However, it should be added that in terms of the “export” value of cultural psychology, perhaps nowhere is this greater than in neuropsychology or genetics, because these two fields are so comparatively new and their assumptions of universality so strong. As noted by Kitayama et al. ([Chapter 3](#), this volume) and others (e.g., Hackman, Farah, Meaney, 2010), culture and socioeconomic status seem to affect, for example, what brain regions get activated when people think of the self versus a close other, process faces, or perform certain language and executive function tasks. “Maps of the *human brain*” constructed from samples of middle-class Westerners may look different from those that would be constructed if neuroscientists aggressively pursued cross-cultural samples. If such aggressive sampling is pursued, cultural psychologists will hopefully be able to contribute to understanding the cultural differences and similarities that explain why conflicting (and nonconflicting) results emerge. Though the neuroscience field is young, reconciliation of results still must be done in a principled—rather than “just so”—fashion, as discussed in the earlier section on the “replication crisis.”

More generally—to the extent that the science warrants it—cultural psychologists may be able to play a role in a paradigm shift to “take back” the brain and genes from the biological determinists. Within psychology (and especially among the mass public), the dominant way of understanding genes and brains is as biological blueprints that determine behavior (Heine, 2017). To the extent that cultural psychologists can show that experience (culture) shapes the brain and expression of genes, they may help reset the dominant paradigm, bringing the pendulum back from a position of strong biological determinism, toward a more moderate position in which we shape our brains and genes in addition to their shaping us.

Beyond the Questionnaire and Lab Experiment

The methodological pluralism of cultural psychology embraces studies that go beyond questionnaires and lab studies. A few are mentioned below.

Field Experiments

In addition to controlled trials run by economists (discussed previously in the “[Replication](#)” section), there are excellent opportunities for researchers to conduct field experiments on their own or as part of larger intervention programs administered through schools, social work agencies, or government “nudge” units (in the U.K., www.behaviouralinsights.co.uk, or the U.S., <https://sbst.gov>; Halpern, 2015). These programs sometimes target a particular cultural group and at other times focus on the general population, which may have many cultural subgroups (Oyserman, 2015). The opportunity for cultural psychologists to propose some interventions, contribute to their design, or simply observe the results allows researchers to study how different types of programs affect people from different cultures. This provides a good opportunity to move into “the real world”—and bring that knowledge back. As Kurt Lewin is credited with saying, “If you want to truly understand something, try to change it.”

Field experiments can be done with not only “normal” individuals but also organizations or with political elites—such as when studying how U.S. Senators explain their votes to citizens (actually, confederates) with different

ideologies (Grose, 2014; Grose, Malhotra, & Van Houweling, 2015) or how bureaucracies respond to citizens' (confederates') requests (Putnam, 1993). Such studies are important, because researchers can and should consider institutions and elites, as well as "normal" individuals, as carriers, shapers, and representatives of a culture.

Analysis of Cultural Products

Cultural products are ripe for analysis. They include the laws that are passed, the advertising techniques used, the news articles written, the goods consumed, the art produced, the stories told, and so on (Harrington & Gelfand, 2014; Imada, 2012; Kashima, [Chapter 2](#), and Markus & Hamedani, [Chapter 1](#), this volume; Morling & Lamoreaux, 2008; Lamoreaux & Morling, 2012; Shavitt, Cho, & Barnes, [Chapter 25](#), this volume). Some examples in [Table 6.2](#) are aggregates (e.g., readership of violent magazines); that is, they represent individual, "independent" decisions made by people that are merely summed together. Others (e.g., the distinctive streetscapes of Japan and the United States) are more collective products; that is, they require some form of collaboration and negotiation among multiple actors to produce. If, as Becker (2008, p. 50) writes, "objects . . . are congealed social agreements or . . . congealed moments in the history of people acting together," we can ask not only what the object itself signifies but also what processes and arrangements brought it about. Such questions can illuminate how a culture(s) works, as the processes bringing about a collective product may be similar or different in the cultures we are comparing.

TABLE 6.2. Examples of Analyses of Cultural Products

Topic	Analysis
Holistic–analytic representation in East Asia versus the United States	Cityscapes emphasize buildings as discrete entities (U.S.) vs. are blended together (Japan). Background (vs. central figures) more prominent in East Asian vs. U.S. art (Nisbett & Masuda, 2003; Miyamoto, Nisbett, & Masuda, 2006)
Violence is legitimated more in certain regions of the United States	Subscription rates for violent magazines, viewership of violent television shows, per capita production of college football players, and state laws relating to corporal and capital punishment (Baron & Straus, 1989)
The rise of guilt and decline of shame in the West	Changing ratio of shame to guilt words in translations of the Bible from 1600 through 20th century. (Cohen, 2003)
The rise of individualism in the United States	Frequency of use for words such as <i>individual</i> and <i>self</i> versus <i>obedience</i> and <i>authority</i> in Google Ngram from 1800 to 2000 (Greenfield, 2014)
Attributions to effort versus talent in the East versus West	Analysis of greeting cards for college graduates praising their smartness versus hard work (Choi & Ross, 2011)
Neighborhood orderliness predicting antisocial behavior	Ratings of physical disorder taken from Google street view correlated with reports of childrens' antisocial behavior (Odgers et al., 2012)
Jewish theology and culture	Analysis of the change over time in the content and cooption of Jewish jokes (Raskin, 2015)
Models of agency in working-class and middle-class culture	Analysis of themes of controlling one's environment versus responding to it in lyrics from country versus rock songs (Snibbe & Markus, 2005)

More Qualitative Methods

More qualitative studies can add a richness and depth that more quantitative studies cannot (Becker, 2017; Luker, 2008; Miller, Fung, & Koven, 2007). They add the *qualia* necessary for understanding what it is like to be encultured in a given society (Shweder, 1997, 2003).

The distinction between qualitative and quantitative studies is not absolute. In qualitative work, there is usually some degree of quantitateness. Statements that “a few,” “a minority of,” “a majority of,” “many,” or “most” informants did a certain thing reflect some sort of tally

the researcher was implicitly or explicitly making. Similarly, our quantitative methods require some qualitative judgment whenever we, for example, analyze the tone, degree of complexity, or affective content of a participant's response. (For that matter, many self-report scales ask participants to quantify subjective judgments that they are, for example, "moderately satisfied with their life" or "extremely in love" with their spouse). In still other cases, we may analyze anthropological data from the Standard Cross-Cultural Sample or Human Relations Area Files, using quantitative methods to aggregate qualitative data.

Summary

In summary, in addition to all the standard operationalization issues one must worry about, cultural psychologists must construct variables that are interpretable and convincingly operationalize a construct when seen through (at least) two different cultural lenses. Thus, cultural psychologists face the additional problem of "translation," broadly defined to include language, behaviors, situations, reference groups, and so on. Cultural psychologists do have one advantage over their more discipline-bound colleagues, though. The field's youth and pluralistic outlook fosters a pluralism in methods as well (Cohen & Kitayama, Introduction, this volume). All methods have their weaknesses. However, cultural psychologists have a full toolkit of techniques that complement each other in their strengths and are useful for initial exploratory work and for producing the convergent evidence across methods that makes for convincing social science arguments.

INTERPRETATION

Careful consideration of causal, sampling, and operationalization issues should lessen (but not eliminate) difficulties of interpretation after data are collected. There are inevitable problems with any method. However, other interpretational issues may arise, independent of artifacts from any one study. Three issues considered below involve (1) how we interpret

similarities and differences between cultures, (2) how we might construct a mental checklist or do thought experiments to examine our disciplinary biases, and (3) how we interpret data that do not converge.

Understanding Similarities and Differences

Cultural psychology dissents from mainstream psychology in its presumption of universality. However, it is also committed to finding connections between cultures. This is both a practical matter in terms of making studies interpretable and a theoretical matter concerning how we think about similarity and difference.

Controls and Boundaries

One issue in thinking about similarities and differences involves the importance of both boundary conditions and comparison conditions. Because of various response bias effects, a culture main effect may be difficult to interpret by itself. For example, if one is measuring performance on some test, it is good to have definable parts of the test in which one expects a cultural difference and definable parts in which one expects either no difference or a reversal. Thus, if one expects culture *A* to show better memory than culture *B* for social stimuli, it is helpful to show that there are no differences (or a reversal) for nonsocial stimuli. If culture *A* does better than culture *B* for social stimuli but there is no comparison condition of nonsocial stimuli, one cannot rule out the possibility that culture *A* simply took the task more seriously.

Besides ruling out response biases, comparison conditions or comparison variables are also theoretically meaningful, because they put boundaries on the phenomenon one is studying. Control conditions that are expected to produce similarities serve as an “anchor” for the way we think about the two cultures, preventing readers from drifting off into extreme relativism.

The Necker Cube of Culture

A second issue about similarities and differences is more abstract, but it goes to the heart of what cultural psychology is or will become; that is, to the extent that cultural psychologists can discuss both similarities and differences across cultures, it will be a richer field than if they discuss only differences (see also Norenzayan & Heine, 2005; Konner, 2007).

Cultural differences are embedded within similarities, and cultural similarities are embedded within differences. Depending on how we look at it, the similarities can look greater or the differences can look greater. A rich cultural psychology will force us to look at the “Necker cube” of culture. Like the surfaces of the Necker cube, what pops out at us in our understanding of cultures will shift back and forth in terms of the ways the cultures are similar at one level and different at another. The implication is that cultural psychologists may design their research programs to be strong on both *integration* and *differentiation*. Phenomena that are different on the surface may have a similarity in terms of their deeper structure, and cultures that are similar on the surface may be quite different in their deeper structure. An example of some now-classic work on choice, dissonance, and the self helps illustrate the point.

Starting in the 1990s, Heine and Lehman (1995, 1997a, 1997b) and colleagues (Falk & Heine, 2014; Heine, Kitayama, & Lehman, 2001; Maddux et al., 2010) began publishing an astonishing line of research, showing that some very robust self-enhancing biases did not seem to operate in Japan. One finding involved the “spread of alternatives” paradigm from cognitive dissonance research, in which participants make a choice, then rationalize that choice as a way to protect their self-esteem. Heine and Lehman (1995, 1997a, 1997b) showed that this classic effect did not hold among Japanese, presumably because dissonance effects, like other self-enhancing biases, did not operate in this population.

Two lines of research qualified Heine and Lehman’s (1995, 1997a, 1997b) finding in important ways, however. In one, researchers replicated Heine and Lehman’s findings when participants made choices for themselves. However, they showed that when making a choice for others, the findings reversed: Asian Canadians rationalized their choices, and European Canadians did not. Both groups rationalized their choices, but for very different reasons—European Canadians to protect an agentic self that knows what it wants and gets it, Asian Canadians to protect an interdependent self

that is sensitive to others' desires. Making the point stronger, Hoshino-Browne and colleagues (2005) showed that a traditional self-affirmation task (which bolsters the self and typically wipes out the need to rationalize for European Canadians) had no effect on Asian Canadians. Instead, only a new self-affirmation task that bolstered the interdependent self and shared values wiped out dissonance effects for Asian Canadians.

In a separate but related line of work, Kitayama, Snibbe, Markus, and Suzuki (2004) explored the way choice threatens a person's self in different ways for Japanese and for Americans. A bad choice threatens an American independent self, because it means the self is not competent or efficacious (cf. Savani, Markus, & Conner, 2008). A bad choice threatens a Japanese interdependent self, because others may think the person is foolish. Kitayama and colleagues (2004) replicated the results of Heine and Lehman (1997a), showing no dissonance effects among Japanese in the standard dissonance paradigm. However, they found that when Japanese participants were first forced to situate their choices by thinking about self-relevant others and what those others' preferences would be, dissonance effects appeared in full force. Even putting participants in front of a poster with schematic line drawings of faces was enough to prime such concerns and produce dissonance effects among Japanese participants (see also Imada & Kitayama, 2010; Kimel, Grossmann & Kitayama, 2012; Na & Kitayama, 2012).

The work by Hoshino-Browne et al. (2005) and Kitayama et al. (2004) was not a rejection of Heine and Lehman's (1997a) finding. It extended the finding by integrating (showing similar processes of rationalization following self-threat) and differentiating (showing how choice involved different types of threats to different types of selves for the two groups), giving a richer picture of self-threat, rationalization, and the meaning of choice in the two cultures. Looking at these lines of research as a whole is like staring at a Necker cube, with cultural similarities or differences "popping out" at us, depending on how we look at it.

Disciplinary Biases: Creating a Mental Checklist

As psychologists, we have certain disciplinary biases. A person walks through a door and we ask, “Why did he or she walk through that door?” We are less likely to ask, “Why is there a wall there? And how did the door get put in it?” We see individuals acting in the world and look for causes of their behaviors in terms of preferences and attitudes. We are less likely to ask about institutions that constrain those preferences and choices.

Once we start asking about institutions and how they structure choices, the questions and hence answers change. Such a focus often leads us to understand phenomena in a new way, bringing different issues to light. A few examples follow:

1. Europeans have higher organ donation rates than Americans. However, this is not necessarily because Europeans are more beneficent than Americans, but because donation in Europe is the default option and one must affirmatively elect not to be a donor. Of course, one can ask why Americans and Europeans have different default options. It may have to do with their levels of beneficence. Or it may have to do with different attitudes toward the intermediating institution: for example, Americans’ long-standing suspicions about “intrusive” government.

2. Americans and Europeans also have very different leisure habits, with Americans, on average, working an extra 300–400 hours per year compared to some of their European counterparts. Interestingly, this was not always the case. Economists Alesina, Glaeser, & Sacerdote (2006) argue that the difference emerged only in the 1960s, as unions in Europe’s declining industries pushed for reduced hours to increase the number of people employed (see also Green & Potepan, 1988). Thus, the U.S.–European difference in leisure habits may have to do with different attitudes toward leisure. Or it may have to do with differences in the strength of organized labor, different strategies pursued by unions, or different attitudes toward unemployment and the fairness of markets. If there is a difference in attitudes toward leisure among Europeans and Americans now, it may be an *effect* of constraints on working hours (to combat unemployment) rather than a cause.

3. Households in Protestant countries of Europe have more debt than households in Catholic countries of Europe. This may be because Protestants have more profligate attitudes toward borrowing. Or it may be because

banks and other organizations are more likely to lend money in Protestant countries. Interestingly, banks and organizations in Protestant countries seem more likely to extend credit, because their rights as creditors are better protected in Protestant (vs. Catholic) countries (D. Cohen et al., [Chapter 22](#), this volume). Thus, in Protestant countries, historical attitudes stigmatizing debtors likely led to pro-creditor laws and institutional arrangements; these pro-creditor arrangements increased the willingness of banks to lend; and with a greater supply of credit available to them, people then overborrowed. Thus, there is likely a causal connection between attitudes and behaviors, but it is an attitude → institutions → behavior link that inverts the usual attitude → behavior relationship. Protestants' greater indebtedness probably results not from Protestant attitudes favoring borrowing, but rather from Protestants' historical stigma *against* borrowing. One's understanding of Protestant household indebtedness is thus completely different once the influence of intermediating institutions and the *supply* side of credit relationships are taken into account.

At various stages of the research, it is useful to run through questions such as (1) What are the institutions constraining individuals' choices?; (2) What is a "supply" side explanation for the pattern of behavior, or if the working hypothesis is a "supply side" explanation, ask yourself what a "demand" side explanation would be?; (3) Do differences in some target behavior result from different cultures' attitudes toward the target behavior, or from different cultures' attitudes toward intermediating institutions (e.g., governments, unions, markets, or banks)?; (4) Conduct a thought experiment: As Becker (2008) proposed, imagine society as a machine designed to produce exactly the outcomes you have observed. How does the machine work in all its moving parts? Because "we often study 'problem situations,' the machine's product will often be something we wouldn't in fact want to produce" (p. 39), but we will learn something by thinking through how such a "machine" might work.

Partly this mental checklist is a way of examining the data in front of us through other lenses. Partly it is a matter of asking the more painful question about what data we did not collect. If cultural psychology is going to converse with other disciplines, we need to be able to ask (and answer) such questions. To be clear, we do not need to abandon our perspective,

adopt another discipline's biases, change our topic of study, or become all-encompassing in our analyses. We probably have more to contribute as good psychologists than as mediocre anthropologists, sociologists, or economists. However, we should understand our biases and think about interpreting the data we collected—and did not collect—from others' perspectives.⁶

What Happens If My Data Do Not Converge?

The answer to all methodological problems lies in thinking through our theories and collecting convergent evidence using multiple methods. But what happens if the data do not converge? What happens if data from one method point to different conclusions than data from another method? This could be simply random error. However, we also need to investigate whether this divergence is a result of artifacts, or whether it is telling us something meaningful, and if so, what?

Artifacts

The first step involves investigating possible methodological artifacts and possible differences introduced by different sampling techniques and operationalizations in different studies. Also, culture researchers have to watch out for various methodological artifacts because of the types of data with which we sometimes work. For example, statistical artifacts arise from working with aggregate data and grouped data. There are fallacies in going from group data to individual processes (“More religious states also consume more pornography; therefore, religious people must look at more porn”) or from individual effects to group differences (“Within a group, skin tone has a strong genetic basis; therefore, the difference in skin tone between people living in sunny Florida and cloudy Michigan must be genetic”). The fallacies are easy enough to catch in examples from the last sentence. But they are not always easy to catch and sometimes get frequently repeated. (Every 4 years, political commentators observe wealthier states voting for Democrats, then infer that wealthy people lean Democratic. In general, however, they do not).

We may also collect data on college students and complement this with surveys of the general population. There may be artifacts here as well. The homogeneity of college student samples can lead to problems with restrictions of range, obscuring relations between two variables that are correlated in the wider population. For example, at elite, liberal universities, there may be little correlation between parents' education and students' social attitudes, though in the wider population, where there is substantial variation on both variables, there may indeed be a correlation. On the other hand, the homogeneity of student populations can also reduce "noise" or extraneous variation, allowing us to detect effects that might otherwise be drowned out in the heterogeneity of a national sample.

Many problems are much more subtle than these. And when data do not converge, there may be statistical artifacts affecting one study or another.

Does the Nonconvergence Represent a Real Cultural Phenomena?

Suppose, however, that no obvious methodological issues or artifacts explain nonconvergent results. Obviously, we need to collect more data, but in what direction do we go? To decide this, we have two choices: believe our theory or believe our data. (Here we run into an actor–observer problem. Einstein's dictum was that, as researchers, we believe our theories more than our data. However, observers believe our data and not our theories [Galison, 2004].) If one still believes the theory, the next study should test the hypothesis in a new way and, one hopes, provide clear results and also reconcile any conflicts.

Suppose, however, that one believes the data. There may be good reasons for conflicting results in the studies, because the story may be more complex than originally thought. As noted, individuals from different cultures may have similar attitudes but behave differently because of different institutional or situational constraints; conversely, they may have different attitudes but behave similarly because of similar institutional arrangements or situational affordances. But these are only two possibilities. A few other examples below—which all revolve around the *social, interactive* nature of human action—

hint at the wealth of possible explanations (see also D. Cohen et al., in press):

1. A researcher finds that public behavior and cultural products tend to support a cultural norm X . However, in private attitude surveys, people do not support norm X , and in fact support norm Y . It could be that, for reasons discussed previously, attitude surveys just provide weaker results than analyses of behavior. However, another possibility is that people may be in a state of “pluralistic ignorance” (Miller & Prentice, 1994). Everyone in a culture may be against norm X but may think that everyone else supports it. As a consequence, people behave in ways consistent with the norm, even when no one privately believes in it. Miller and Prentice provided examples of this involving norms about drinking, racial attitudes, and other topics; and Kuran (1995) proposed pluralistic ignorance as a force sustaining communism in Eastern Europe, apartheid in South Africa, and the caste system in India. (On people’s conformity to descriptive norms as opposed to personal beliefs, see also Chiu & Hong, [Chapter 26](#), this volume; on people’s tendency to focus on what is public and common knowledge, see Stasser & Titus, 1985; Thomas, DeSciolo, Haque, & Pinker, 2014; also see Y. Kim, Cohen, & Au, 2010, on greater common knowledge effects in Asian cultures; on norms vs. values, see Minkov & Blagoev, 2012).

2. Another example: Behavioral effects may be bigger than what we would expect from attitudinal data, because many behaviors are *social* behaviors. *They necessarily involve other people and require their participation*, which means that there will not be a simple linear relationship between persons’ internal predispositions and the actions they produce.

Take a hypothetical case of two cultures differing in the proportion of people who have an aggressive mindset: In culture A , 2% of the people have an aggressive mind-set; in culture B , 6% do. Suppose further that interpersonal interactions follow something like an “it takes two to tango” rule (Daly & Wilson, 1988; Nowak, Gelfand, Borkowski, Cohen, & Hernandez, 2016). In culture A , for any single random encounter, there is a .04% chance that aggressive people will meet and a fight will occur. In culture B , there is a .36% chance of such people randomly meeting and fighting. The 3-to-1 difference in attitudes becomes a 9-to-1 difference in

behavior, because the “two to tango” rule means that differences in behavior go up as a function of the square of the differences in attitude.

This effect is magnified further for any behavior requiring the meeting of three like minds; a three-to-one difference in attitudes would become a 27-to-1 difference in behavior. Theoretically, differences in behavior would go up as a function of d^n , where d is the ratio of the difference in attitudes, and n is the number of people of similar mindsets who must meet to produce the behavior. The broader point is that differences between cultures in people’s dispositions do not necessarily produce differences in behavior of the same magnitude, because social behaviors are some function of person A ’s disposition, person B ’s disposition, *and their interaction*.

That interactions are key also seems to be *one* reason cities scale superlinearly for many good and bad outcomes. Cities increase opportunities for people to interact, intensifying the potential for both good and bad results. As a city’s population increases, levels of productivity, inventions, and creative outputs—as well as traffic, crime, and disease—increase not just absolutely but on a *per capita* basis (Bettencourt & West, 2010; Bettencourt, Lobo, Helbing, Kuhnert, & West, 2007). Almost surely, self-selection and the heterogeneity of people engaging with each other produce some of these effects (Glaeser, 2012; Page, 2010), but city size or density by itself seems to increase the frequency of interactions, producing both positive and negative outcomes (Schläpfer et al., 2014).

3. Finally, “tipping point” models—in which norms and behaviors change when they hit some critical threshold—operate as well according to nonlinear principles. Such models have been proposed for explaining neighborhood racial segregation, the diffusion of innovation, the exodus of males from professions when “too many” women enter, and abrupt changes in social and political systems (see, e.g., D. Cohen, 2001; Kuran, 1995; Pan, 2015; Schelling, 2006).

These examples—public conformity to norms that are not privately believed, common knowledge effects, the multiplicative nature of behaviors when it takes two (or more) to tango, superlinear growth due to increased interaction, and tipping points—are all interesting, nonartifactual explanations for results in which there is a disjunction between the private and public, between attitudes and behavior, between aggregates of

individuals and collectively produced effects. There are likely many other effects that also point to interesting cultural phenomena. Researchers wanting to examine such phenomena can devise follow-up studies to test their post hoc explanations for the current pattern of divergent data.

Summary

In summary, interpretation issues facing cultural psychologists are many. Using multiple methods makes for a convincing argument when the data converge across them. However, data do not always converge. At that point, the researcher needs to figure out whether the lack of convergence is artifactual or hints at interesting and important phenomena yet to be uncovered.

Interpreting our data in different ways, we can examine phenomena in ways that go beyond the disciplinary biases of psychology. When we consider, for example, institutional constraints, attitudes toward intermediaries, and “supply side” explanations for our effects, the questions we ask change, and we may see phenomena in a new light.

A coherent social science explanation will also be strong in the way it integrates and differentiates. The researcher staring at the Necker cube of culture will discover how similarities are embedded within differences, and how differences are embedded within similarities. This similarity–difference perspective makes our field richer scientifically.

ON SCIENCE, POETRY, AND POLICY

The similarity–difference perspective is important for another reason. As noted earlier, Eliot (1998) wrote that good poetry makes the unfamiliar familiar and the familiar unfamiliar. Spiro (1990) appropriated this for the study of culture. To make the unfamiliar familiar and the familiar unfamiliar by embedding differences within similarities and similarities within differences is good poetry. It is good science. And it is good policy. Ultimately, this familiar–unfamiliar, similarity–difference approach is what may prevent cultural psychology from degenerating into cultural

stereotyping, or from being used as such. First, to the extent that we as a society come to see another group's practices as similar to our own (making the unfamiliar familiar), we lessen the distance between us and the Other. Second, to the extent that cultural psychology encourages people to step outside their own frames of reference (making the familiar strange), we also likely encourage humility about our own practices and may be less quick to judge the Other.

Cultural differences are real, and they will be noticed. (J. Cohen [1988] defines a medium effect size as “visible to the naked eye” and many of our effect sizes are at least this big.) Given, then, that differences will be noticed, how does one interpret them?

One can either (1) view differences in terms of the dominant discourse, in which case comparisons with the Other are likely to be invidious, or (2) one can approach difference by assuming (at least initially) that the difference reflects some meaningful, coherent way of seeing the world that is different from one's own. Cultural psychology is about figuring out what those meaningful, coherent ways of seeing the world might be.

To deny that differences exist is to assume our culture's values are universal (or will be universal, as soon as those other people “come around”). To deny that differences will be noticed is to assume that people are so blind that they will not see what is “visible to the naked eye” in our increasingly pluralistic societies and interconnected world (A. Leung & Koh, [Chapter 21](#), this volume). Ultimately, one views differences through the prism of the dominant discourse, or one tries to study and understand how other ways of seeing the world can be sensible, cogent, and meaningful. Cultural psychology does *not* imply moral relativism. (It does not imply that there are no moral standards; setting aside morality, it does not even imply that all cultural patterns are adaptive; see the “[Causation](#)” section.) It does, however, prize a certain humility and urges us not to rush into either actions or judgments propelled by our own certitude (Shweder, 2003, 2017).

CONCLUSION

Researchers confront choices, because every method has its trade-offs. The methods themselves have assumptions built into them about what culture is.

For example, they contain assumptions about how much we conceive of culture as being in the person versus “out there”; about what is culture and what is confound; about how readily cultural rules can be articulated; about what will translate across cultural worlds; about units of analysis and who or what has agency; and so on.

As culture researchers, we inherit all the problems of the disciplines in which we were trained, plus those that come with any attempt to understand, operationalize, sample, or interpret across cultures. We face challenges, but working in our field also provides some serious advantages. Cultural psychology is pluralistic in its methods, so its outlook is not limited by the use of a single paradigm or methodology. There is not yet, and it is hoped never will be, a dogma to which cultural psychologists must adhere. And we are willing to listen to other fields, even if some are not (yet) willing to listen to us.

Finally, there is still plenty of “low-hanging fruit.” There are whole areas of the world yet to be explored by cultural psychologists, and a huge range of topics yet to be studied. In this second edition of the *Handbook*, about half of the chapter topics have changed since publication of the first edition (there are new chapters on gene \times culture coevolution, money, innovation, terrorism, race, cultural learning, etc.); other chapters cover basic topics for any sort of psychological approach but offer very different perspectives than those offered in the first edition. So, the field grows. Methodologically, the field is open to the discovery of new techniques and innovative ways of thinking about problems. The challenges we face and the opportunities we have are two sides of the same coin. If we cultural psychologists have yet to find good answers to some of our methodological issues, it is in part because the field is still young (Cohen & Kitayama, Introduction, this volume). However, this same youth makes our field open, pluralistic, and full of opportunities.

NOTES

1. Strong crossover effects increase the test statistic for an interaction. For example, in a 2×2 design, all else being equal, the test statistic for an interaction will be greater than the test statistic for the largest simple effect, if the smaller simple effect shows a reversal at least 42% as large as the bigger simple effect (Abelson, 1995).

2. One might consider any difference between two cultural groups as definitionally a “cultural” difference. However, in this chapter I stick with more conventional notions that there are some differences one would not want to call “cultural”; thus, there is a continuum of differences running from “more cultural” to “less cultural.”

3. If one were primarily focusing on the relationship between crop volatility and fatalism, one might gather data from multiple countries that differed widely in the volatility of their crops. However, for this example, pretend that for reasons discussed elsewhere, the researcher wanted to focus in on these two cultures.

4. For practical difficulties beyond a lab psychologist’s worst nightmares (1% compliance rates, 1% participation rates, disregard for control conditions, monsoons, etc.), see Karlan and Appel’s (2016) *Failing in the Field* or Banerjee et al.’s (2016) account of difficulties in scaling up interventions. Then again, one person’s error is another’s topic of interest, so cultural psychologists with an organizational bent might want to study why some programs operate smoothly and nimbly in one place but with torpor, inefficiency, or sabotage in another.

5. A note should be added about other types of experiments done primarily by economists and political scientists. In a “natural experiment,” the independent variable is not designed and implemented by the experimenter. Some other process creates the manipulation and “random assignment” to conditions. For example, rainfall makes some harvests rich and others poor; colonial powers draw a seemingly arbitrary line, splitting a single group into two distinct political units with different laws, institutions, and norms (Posner, 2004); twins are separated at birth and adopted into different familial environments; lotteries decide which applicants to a program move to different neighborhoods or get into certain schools (Chetty, Hendren, & Katz, 2016); and so on. Such studies can be extremely powerful when it is simply not possible for an experimenter to randomly assign people to cultures or to manipulate the presence versus absence of certain environments or institutions. However, “natural experiments” vary in their degree of persuasiveness, because some seemingly arbitrary cutoff points are not arbitrary (Stein, 2008); some “random assignments” actually have self-selection effects (Eisenberg & LoPucki, 1999; Leigh, 1994) or other “de-randomizing” processes (Hall, 2010; Thorley, 2015); or some natural manipulations have consequences for potentially relevant confounding variables (Gladwell, 2008). Relevant to the last point, it may also be difficult to cleanly isolate the causal impact of one factor when that factor engages other processes—as in twin studies that cannot actually cleave nature from nurture but instead often explore a dynamic of nature-through-nurture as children self-select into certain environments or as environments treat children with similar genetic endowments similarly (Nisbett, 2010; Rutter, 2007; Saltz & Nuzhdin, 2014; Worthman, 2010).

Relatedly, economists and political scientists often attempt to measure a causal effect and deal with measurement error and omitted variables by using an “instrument” variable to estimate the effect of X on Y . There are a number of assumptions that go along with “instrumenting” and readers can see Stock and Watson (2003) or Kenny (2012) for details. But suffice it to say there is a range in how credible such analyses are. Some can be quite good; others can seem good but actually not be (Stock & Watson, 2003); and still others seem dicey even on the surface. An example of the last was the headline-making *working paper* from Cornell economists suggesting that television caused autism (Waldman, Nicholson, & Adilov, 2006). Television watching was not measured directly; instead, researchers used rainfall as the instrument variable for TV watching (kids watch more TV when it rains) and estimated that TV watching accounted for a large portion of the geographic variability in autism. Some (though not all) media outlets barely mentioned the instrumentation part (ABC News, 2007). The academic journal article published later was more circumspect and mentioned TV as only one of several possibilities (Waldman, Nicholson, Adilov, & Williams, 2008).

6. Frederick (cited in Levitt & Dubner, 2015) proposes that “supply-side” versus “demand-side” explanations may reflect a disciplinary bias. For example, psychologists (and non-economists) may focus more on demand-side explanations for phenomena (e.g., more apples are eaten in culture A than in culture B, because people in culture A like apples more). Economists, on the other hand, may focus more on supply-side explanations (e.g., more apples are eaten in culture A, because farmers in culture A can grow apples more cheaply and efficiently). Both may be true—and it is likely that factors relevant to both supply and demand are not independent but instead may influence one another.

CHAPTER 7

Culture and Intelligence

Richard E. Nisbett

A person's total score [on the Raven Progressive Matrices Test] provides an index of his intellectual capacity whatever his nationality or education

—RAVEN, COURT, AND RAVEN (1975, p. 1)

Different cultures specialize in different intelligences. People in modern cultures have higher IQs and are in fact considerably more intelligent than people in earlier times. Middle-class socialization prepares children for professional careers; lower-class socialization prepares children for nonprofessional careers. Blacks and whites differ in IQ, but the difference is decreasing. There is no evidence that Asians or Asian Americans, at least prior to high school, have IQs that differ much from those of European Americans. Asian Americans' career success, which greatly exceeds that of European Americans, is primarily due to hard work and motivation. Non-IQ aspects of intelligence, including creativity and possibly practical intelligence, differ across cultures. Analytic, logic-related skills are more common in Westerners than in Easterners. Holistic perception and reasoning are more common in Easterners than in Westerners, and their virtues and vices are essentially mirror images of those for analytic skills. IQ will continue to increase in the future—at a more rapid rate the less economically developed the country. Our conceptions of IQ are going to change: They will continue to emphasize the categorization, abstraction, and hypothesis-testing brought to the fore by the literacy and numeracy training required for success in the Industrial Age; but IQ tests will also begin to include heuristics necessary for the Information Age, derived from statistics, scientific methodology, and economic and psychological concepts.

Here is an IQ test for a 19th-century Sioux Indian. Do your best to answer each question.

What's the best way to ensure that the tribe can always make a fire in short order?

In what circumstances is it most effective to kill a large number of buffalo by starting a prairie fire and in what circumstances is it best to force them off a cliff?

Your tribe has relocated temporarily to a new part of the country where you have never lived before. You must make new arrows immediately. Would it be best to use ash trees, which are abundant in this new territory or send scouts out in several locations in search of locust trees, which of course make much better arrows? What are the most important considerations for such a decision? What if the best scouts are also the best arrow makers?

How would you decide on the best people to send on a raiding party? What are the most important attributes in the leader if (a) the main purpose of the raid is to obtain horses or (b) the main purpose is to drive the other tribe out of your territory?

How did you do on this IQ test? I doubt I could have scored above the 2nd percentile—and I could do that well only because I'm the author of the test!

But maybe you feel that the test is unreasonable because it's designed for people belonging to a different culture. So let me give you a few problems from the Army's Alpha IQ test.

1. Seven-up is played with
rackets cards pins dice
2. The Leghorn is a kind of
horse chicken fish cattle
3. Jess Willard is a
fortune-teller labor-leader pugilist singer
4. The Union Commander at Mobile Bay was
Dewey Sampson Schley Farragut

How did you do on that test? I'm guessing not well. But don't feel bad. The Army Alpha is the IQ test given to recruits in World War I.

You may be feeling annoyed at this point. You already knew that different cultures make different demands on their members. Please accept my apologies. I'm now going to give you an item very much like those on

Raven's Progressive Matrices test (see [Figure 7.1](#)), which is widely used today by psychologists, including Richard Lynn, in his effort to compare the IQs of people of different nationalities and races.

FIGURE 7.1. A problem similar to those on Raven's Progressive Matrices test. From Flynn (2007). Inducing the rule that generated the change from the top-left figure to the top-right figure in the box allows you to figure out what figure among the six to the right of the box would derive from a comparable change to the figure on the bottom left of the box. From Flynn (2007). Reprinted with permission from James Flynn.

The skills that are relevant to solving problems on Raven's test are working memory, skill at dealing with abstractions, and executive control. It was obvious to the IQ testing community that such abilities owe nothing to culture. Everyone has seen circles and squares and triangles. So a 19th-century Sioux Indian might do well on that IQ test, no?

No. He or she would have scored little better than you or I would have scored on a Sioux IQ test. You have to have modern schooling to do well on any IQ test, including most especially Raven's Progressive Matrices test. A study of African children who did not get to go to school until fairly late found that they gained 10 points on the Raven after a few months of school. Among other things, school teaches you how to think about abstractions. It also teaches you about rule induction, and may improve working memory.

IQ GAINS OVER TIME

IQ tests are one of the ways we measure intelligence. They have a long history and good validity—they correlate moderately well with academic

achievement and with performance on a host of different kinds of jobs. IQ tests are narrow in several respects and don't capture everything we consider to be intelligent behavior. But despite the fact that IQ tests and academic achievement tell us much less than we would like about intelligence, they are both important and incontestably reflect intelligence of a kind. And we have reams of data about each. So it is on these measures that I concentrate.

IQ, no matter how it's measured, has been going up in the rich countries for at least 100 years. Scores for 18-year-olds on the Army's IQ test went up 12–14 points between the start of World War I and the start of World War II. [Figure 7.2](#) shows gains from the end of World War II to 2002 in the United States on the Raven and on the subtests of the Wechsler Intelligence Scale for Children.

FIGURE 7.2. WISC IQ test Full Scale scores and subtest scores and Raven Progressive Matrices scores from 1947 to 2002 for the United States. From Flynn (2007). Reprinted with permission from James Flynn.

The gain has been more than one standard deviation in the postwar period for Full-Scale Wechsler IQ. The mean has remained 100, because the mean of an IQ test at any one time is *defined* as 100. And since raw scores on IQ tests have been steadily increasing, they have to be constantly renormed in order for the mean to remain 100. A person getting an average number of problems right on an IQ test in 1947 would have gotten a Wechsler IQ of 100. A person getting the same problems right on the 1947 test today would have an IQ of 83. One might wonder whether a person with that IQ could

finish high school. A person getting an IQ score of 117 in 1947 would get a score of 100 today—down from university material to more like the community college level.

As for the Raven test, scores went up almost two standard deviations between 1947 and 2002. The Raven test is not culture-free. The Raven is drenched in culture. The Raven is all about culture.

But have we really gotten smarter over the past 60 or 70 years? Certainly not two standard deviations smarter, as suggested by the Raven improvement. But one standard deviation, as suggested by Wechsler Full Scale? Any smarter at all?

The answer is yes, we have gotten smarter—though quantifying the real-world changes in intelligence would be difficult and has not been attempted. Consider the Comprehension subtest. This is not paragraph comprehension but rather comprehension of the way the world works. A typical item would be, “Why do doctors go back and get more education?” A child who can answer that question is smarter than a child who can’t. Today’s children score the equivalent of 11 IQ points higher on the Comprehension subtest than the children of 1947. Or consider the Similarities subtest. A typical item would be, “How are revenge and forgiveness alike?” A child who can answer that is smarter than one who can’t. Ability to handle similarities went up by the equivalent of 23 points. Vocabulary went up very little between 1947 and 2002 for children (perhaps because the vocabulary level of school texts kept declining over most of that period). But it went up a standard deviation for adults, probably because of the great increase in tertiary education. Words encapsulate concepts, and people who have a large stock of concepts are smarter than those who have a smaller stock of them.

Why have we gotten smarter? A big part of the answer is that more and more people are getting more and more education. In 1920, fewer than 20% of Americans were educated through high school. By 1983, more than 80% were. And material at a given level of difficulty is taught earlier and earlier. In 1900, it was understood that college students were not ready for calculus until their senior year. Today, schools routinely teach calculus to 16-year-olds. Part of the reason for the 17-point gain on the so-called “Performance” subtests—Block Design, Object Assembly, Picture Arrangement (make the pictures tell a comprehensible story), and Picture Completion (provide the missing part of the picture)—undoubtedly has to do with the increasing

amount of exposure to complex visual content in the schools and via the computer. The gains on the Raven are almost surely due in part to this increase in exposure to visual materials. In fact, there are materials created for first graders that are practically proto-Raven items.

Beyond formal education changes, the wider culture makes heavier demands on intelligence than formerly. Computer games are an obvious example. *I Love Lucy* was a terrific television show, but it made few demands on higher intellectual skills. Much of modern television does make such demands. At any rate, I find myself constantly asking my family members what is going on!

At one level, the answer to why we have gotten smarter, and gotten smarter in the particular ways we have, is that when the economy demands particular cognitive improvements, the culture can be expected to rise to meet those demands. The switch from an agriculture-based economy to an industry-based economy meant that everyone had to be able to read and do math. School became compulsory through late elementary school. Improved thinking skills—working with abstractions, inducing rules from examples, thinking about counterfactuals—were an unintended and inevitable consequence of literacy and numeracy. And those skills proved enormously useful for jobs dealing with relatively high levels of complexity.

Will the gains on contemporary IQ tests go on forever? The IQ gains are continuing in the United States and the United Kingdom, but they may be topping out in Scandinavia (Emanuelsson, Reuterberg, & Svensson, 1993; Sundet, Barlaug, & Torjussen, 2004). Nations in which modernization began during the early to mid-20th century have been showing large and continuing gains. Urban Argentines (ages 13–24) made a 22-point gain on Raven's Progressive Matrices test between 1964 and 1998 (Flynn & Rossi-Casé, 2011). Children in urban Brazil between 1930 and 2002 (Colom, Flores-Mendoza, & Abad, 2007), in Estonia between 1935 and 1998 (Must, Must, & Raudik, 2003), and in Spain between 1970 and 1999 (Colom, Lluís-Font, & Andrés-Pueyo, 2005) have all made large gains that are continuing. IQ gains for countries that have only recently begun to modernize, such as Kenya (Daley, Whaley, Sigman, Espinosa, & Neumann, 2003) and the Caribbean nations (Meisenberg, Lawless, Lambert, & Newton, 2005), show extremely high rates of gain.

THE FUTURE OF INTELLIGENCE

If the rate of gain that is characteristic of countries at different levels of economic development were to continue, the IQ differences between nations might be obliterated within a generation or two. But I am confident that IQ is going to be a moving target. IQ tests will change, because the culture is already demanding new intellectual skills that are not represented on IQ tests and will demand yet more new thinking tools in the future. These changes are due in part to the information revolution. Effectiveness, both in many professions and in everyday life, requires skills at systematic gathering and analysis of information and the ability to construct arguments based on that information. Some of these tools are statistical in nature (population, sample, sample bias, randomness, law of large numbers, normal distribution, standard deviation, statistical significance, regression to the mean, base rate, correlation), others are economic (cost–benefit analysis, sunk cost, opportunity cost, loss aversion), and still others draw on concepts from scientific methodology (artifact, control group, confounded variable, self-selection, the concept that correlation does not establish causality, independence of observations, randomized control experiment, natural experiment, multiple regression analysis, linear versus curvilinear models).

People are going to be expected to know how to apply such thinking tools to everyday life and to problems in business and finance, as surely as the citizen of 1870 was expected to be able to read and write. Education will have to change, of course, before IQ tests will begin to measure ability to use such concepts. Such education ought to begin no later than high school. Unfortunately, even college courses are not taught so as to make it clear how to apply these concepts to real-world problems. My joke about statistics is that it is taught so as to prevent, if at all possible, its escape into everyday life. I have written a book teaching some of the newly essential concepts in the abstract and showing how to apply them to everyday life problems (Nisbett, 2015). I have also developed an online course with Coursera (Nisbett, 2017) that teaches how to use the same concepts in business and personal life. I hope these efforts hasten the day when all of these concepts will be readily applied to real-world problems that require them.

In any case, it seems clear that the most economically advanced nations are going to demand these skills first and begin to assess them with IQ tests.

When these same tests are given, the citizens of less advanced countries are going to get lower scores than the citizens of more advanced countries.

SOCIALIZING INTELLIGENCE

Of course not everyone in a given nation is aiming for the kinds of occupations that require the highest levels of intellectual skill. Working-class parents may not even know exactly what these demands are, and their socialization of their children is correspondingly different from that of middle-class parents. Moreover, socialization for working-class and underclass blacks is different from that of working-class whites.

Middle-Class Socialization for the Professions

The middle-class parent reads to his or her child much more than does the working-class parent (Center, 2015; Heath, 1982, 1983; Lareau, 2003; Mikulecky, 1996). And the reading is done not just as a form of entertainment but also to encourage connections between what appears on the page and what exists in the outside world. There is a deliberate effort to take what is read in books and relate it to objects and events in daily life. (“See? Billy has a big doggie. Who do you know who has a big doggie?”) Parents also encourage analysis of what is read. (“What will happen next? What does she want to do? Should she do that?”)

Dinner table conversation is like a tennis match: The parent asks a question, the child responds, and the parent comments on the child’s answer. Parents ask their children about the attributes of objects and teach them how to categorize objects based on their properties. (I was once sitting on a plane behind a father and his 4-year-old child and overheard the father ask: “How about pants? Are pants short or long?” Child: “Short.” Dad: “No, Jason, pants are long.”) Middle-class parents teach their children how to evaluate evidence and how to construct an argument.

Middle-class children are well prepared for school. They know how to take information from books, they expect to be entertained by them, and the early grades go easily for such children. They are also well prepared for later

grades that call for analysis and evaluation. They are well equipped for getting the intellectual skills to function at the level of professionals.

Working-Class Parenting: Socialization for Blue-Collar and Clerical Careers

Although working-class children are asked questions about what is read to them, there is not much effort to make contact between the printed page and the world outside. A book might have a picture of a duckling, and the mother might ask the child if she remembers the duck she saw at the lake. But there might be no explanation of the connection between the fuzzy yellow duckling on the page and the full-grown mallards seen at the lake (Heath, 1982). After about the age of 3, children are not encouraged to carry on a dialogue with the reader. Instead, they are told, “Now you’ve got to learn to listen.”

A Philadelphia study illustrates both a symptom and a cause of the social class difference in literacy. It shows that in areas in which almost all adults are college-educated, booksellers had 1,300 children’s books available per 100 children, whereas in blue-collar Irish and Eastern European neighborhoods, only 30 children’s books per 100 children were available (Neuman & Celano, 2001). There could scarcely be a more stark set of figures capturing the social class gap in preparation for schooling.

Activities in the middle-class family are verbalized. The middle-class father showing his child how to bat a baseball says, “Put your fingers on top of each other around the bottom of the bat; keep your thumb in this position here; don’t leave the bat on your shoulder—hold it above your shoulder a couple of inches.” The working-class child gets no such elaborate instructions or experience in going from verbal instructions to physical practice. Instead the child is simply told: “Do it like this; no, like this.” The middle-class mother works from a recipe, which she may read out loud, making connections between what is being read and what is being carried out. The working-class mother is less likely to use a recipe and unlikely to make connections between it and the materials at hand even if she does (Heath, 1982, 1983).

Betty Hart and Todd Risley found that by the time the child of professionals is 3 years old, she has heard 3 million words; by that time, the child of working-class parents has heard only 2 million words (Hart & Risley, 1995). And the level of vocabulary is substantially higher in the professionals' homes.

Working-class children come to school with sufficient preparation to do reasonably well at learning how to read and do arithmetic. But when categorization, analysis, counterfactual reasoning, and evaluation are emphasized in the later elementary grades, such children are at a decided disadvantage (Heath, 1983).

Children who face these difficulties are likely to be demoralized and alienated by junior high and are becoming candidates for dropping out of high school.

The differences researchers have found in socialization for literacy and school helps us understand what happens to children's IQs and academic achievement over the summer, when they are not in school. Overall, the IQs and academic skills of children drop over the summer (Allington & McGill-Franzen, 2003; Phillips, 2000). But the drop is especially large for lower socioeconomic status (SES) children, whose families would not be expected to provide the degree of cultural stimulation over the summer that middle-class families do. The middle-class kids are falling behind less in the summer because, undoubtedly, they are engaging in more educationally valuable activities, such as reading and being read to; listening to stimulating conversation at the dinner table; going to museums and zoos; and taking classes in ballet, music, and even academic subjects. Children in the SES upper quintile actually gain academic skills over the summer (Burkham, Ready, Lee, & LoGerfo, 2004). It seems likely that a significant portion of the class-related academic skills gap can be attributed to the cumulative difference due to lowered intellectual skills over the summer for lower-SES kids, and they never quite make up for it during the school year.

Readers who are mindful of the genetic contribution to IQ differences may be thinking: "How do we know that these differences in socialization practices actually play a causal role in the intelligence and achievement of children? How do we know that higher-SES people have more intelligent children than lower-SES people, not because of what the environment does to them, but simply because they have their parents' fortunate genes?"

Middle-class parents provide their children with more intellectually stimulating environments, but this is because the children's genes make them enjoy doing those things and it is more rewarding to parents too (Nisbett et al., 2012). It must be admitted that this story undoubtedly accounts for a nontrivial portion of what is going on. The environmental differences are to some degree a consequence of higher-IQ genotypes on average for upper-SES parents and lower-IQ genotypes of lower-SES parents.

But we know that the genetic story can't account for the lion's share of the skills gap between the social classes. Lower-SES children have much higher IQs when raised in middle-class families than when raised in the family of origin, and IQs are higher still when they are raised in upper-middle-class families (Nisbett, 2009).

Our confidence about the very substantial role of the environment is crucial to keep in mind when we think about how much we might expect to improve the intelligence of working-class and lower-class children. Because of the adoption studies and the environmental factors that I survey in this chapter, we know that improvements in the environment—including home and school—can make a big difference.

Race and Socialization for Blue-Collar and Clerical Careers

There are substantial ethnic differences to be found within the black population and a wide range of social classes and socialization practices. Black Americans with a Caribbean background tend to have substantial cultural capital (Nisbett, 2009; Nisbett et al., 2012). A very disproportionate fraction of eminent black Americans have such a background. At the other extreme, the very poor in the rural South and inner cities have particularly low cultural capital, and their socialization practices are even less propitious for success in school or work than are those of working-class whites.

Lower-SES blacks tend not to read to their children, and unlike lower-class whites, they make little effort to teach language. Nor do adults label objects or events, or make any attempt to link objects in the here and now with other objects encountered in other contexts (Heath, 1983, 1990).

Meredith Phillips, Jeanne Brooks-Gunn, and their colleagues have looked in detail at studies measuring aspects of the home environment of blacks and whites. The measures that they examined came from the so-called HOME (Home Observation for Measurement of the Environment) scale. Scores on this measure are based on interviewer observations in the home and questions asked of the mother. Factors studied include “learning experiences outside the home (trips to museums, visits to friends, trips to the grocery store), literary experiences within the home (child has more than 10 books, mother reads to child, family member reads newspaper, maternal disciplinary style), maternal warmth (mother kissed, caressed, or hugged the child during the visit) . . . and the physical environment (whether the home is reasonably clean and uncluttered; whether the child’s play environment is safe)” (Phillips, Brooks-Gunn, Duncan, Klebanov, & Crane, 1998, pp. 126–127).

Differences between black and white homes in the two studies were marked, ranging as high as three-fifths of a standard deviation on some measures. Within the black sample, scores on the HOME scale were closely associated with scores of the children on cognitive variables. For one study, the vocabulary score for 5- and 6-year-olds was equivalent to 4 IQ points higher when the mother read to them daily as opposed to not at all. For children in another study, IQ scores were 9 points higher when a family scored one standard deviation above the mean on all the HOME measures (Phillips et al., 1998).

There is every reason to believe that such differences are important for cognitive development. The gap between American blacks’ and American whites’ IQs was about 15 points in 1965. We know that the socialization practices of middle-class black parents are shared to a degree with those of working-class black parents, or at least they were in the 1980s, when Elsie Moore (1986) studied black and interracial children raised by either middle-class black or middle-class white parents. The IQs of black and interracial children raised by white adoptive parents were 13 points higher than those of black and interracial children raised by black adoptive parents, essentially equal to the entire racial gap at the time. Moore found no differences in IQ between black and interracial children whether raised in black or white homes.

Moore's data provide an indication that there is no genetic role in the IQ difference between black children and white children. If there were a genetic basis, the mixed-race children would have been found to have higher IQs than the black children. As it happens, there is much other evidence on this point and it is very nearly uniform in its conclusions: Differences between American blacks with purely African genes and those with substantial European admixture tend to be very slight, even though one would expect that having European genes would be associated with environmental advantages (Nisbett, 1995, 2015).

It would be surprising if the improving economic and social circumstances of blacks in recent decades were not accompanied by corresponding gains in intellectual skills. Indeed, black IQ is now superior to white IQ circa 1960. And since that time, the gap in IQ between blacks and whites has been reduced by more than one-third of a standard deviation. There is every reason to assume that the gap will continue to reduce in size.

Will the black–white gap in IQ ever be literally obliterated? Probably, and possibly quite rapidly. As of the mid-20th century, the Irish in Ireland had IQs at about the level of blacks in America (Macnamara, 1966). English Psychologist H. J. Eysenck (1971) attributed this to the genetic consequences of the fact that the intelligent people had fled Ireland to other lands, leaving the dull-witted—and their inferior genes—behind. (19th-century Americans would have been startled to be told that the Irish in the United States were the cream of the crop.)

The gene pool of Ireland must have been more robust than Eysenck thought, however, because the IQ of the Irish is now equal to that of the English (Flynn, in press) and literacy proficiency for Irish children is higher than that of children in the United Kingdom (Organisation for Economic Co-Operation and Development, 2000). This achievement was no accident. It was the result in part of an intensive education initiative begun in the 1960s. Postsecondary school enrollment in Ireland was increased from 11% in 1965 to 57% in 2003 (Organisation for Economic Co-Operation and Development, 2004). The per capita gross domestic product (GDP) of Ireland now exceeds that of England.

ASIAN AMERICAN–EUROPEAN AMERICAN DIFFERENCES IN IQ AND ACADEMIC ACHIEVEMENT

The academic achievements and high occupational attainment of Chinese and Japanese Americans have inspired speculation about genetic superiority (Lynn, 1987; Rushton, 1995; Weyl, 1969). Although there are claims in the IQ literature that Asians have higher IQs than European Americans, these are based mostly on samples of convenience and, in any case, the numbers range from slightly lower to slightly higher IQs for East Asians than for people of European culture. More probative on the surface are studies of East Asian children adopted by European Americans. Their IQs are extremely high. But Thomas (2017) has shown that the studies suffer from two artifacts—failure to take into account the adoption “bonus” (which in general ranges between 12 and 18 points) and failure to properly norm the IQ tests for Asian adoptees, ignoring the Flynn Effect by using outmoded norms, thereby inflating Asian IQs.

I know of no recent data comparing IQs of Asian Americans and European Americans. However, Flynn (1991) analyzed data from the Coleman Report for the high school graduating class of 1966. That sample, which was large and representative, included a great many Asian Americans. The Asian Americans had very slightly lower IQs than European Americans, but they scored one-third of a standard deviation higher on the Scholastic Assessment Test (SAT). SAT scores may be more reflective of motivational differences (e.g., taking more and higher level math courses) than are IQ tests. Chinese Americans in the class of 1966 ultimately attained occupations of a professional, managerial, or technical nature at a rate 62% higher than those of European Americans! It therefore appears that Chinese Americans capitalize on a given level of intellectual ability much more than do European Americans. When members of the class of 1966 were 32 years old, the average Chinese American—with an IQ in adolescence of a little less than 100 on average—was in an occupation that European Americans required an average IQ of 120 to obtain (Flynn, 1991)!

Flynn also studied the Japanese Americans in the Coleman sample and found them to exceed the European Americans in achievement, though the

superiority was not quite as marked as for Chinese Americans. He found that Japanese Americans having an average IQ of 100 in adolescence were in occupations that European Americans required an average IQ of 110 to achieve.

It's common that it is arbitrary to refer to what Asians accomplish as overachievement. I used the phrase "Asian overachievement" to a Korean friend who had just spent a year in the United States, where his children attended public schools. He expostulated, "What do you mean by 'Asian overachievement'? You should say 'American underachievement' "! He told me that he was astonished when he attended ceremonies at the end of the year for his daughter's school and discovered that an award was given for having done all homework assignments. His daughter was one of two recipients of the award. To him, giving an award for doing homework was about as preposterous as giving an award for eating lunch. It is taken absolutely for granted by East Asians (and almost surely to a considerable extent for Americans of East Asian descent that their children will complete all assigned homework). I think my friend is right to insist that the phenomenon is one of American underachievement. It is quite reasonable to regard high achievement as the default state of affairs and what most Americans do as slacking to one degree or another.

My Korean friend's bemusement touches on the key to understanding Asian achievement magic. Asian and Asian American achievement is not really mysterious. It happens by working harder. Japanese high school students of the 1980s studied 3½ hours a day (Nakanishi, 1982), and it is likely to be, if anything, higher today. The high school-age children of the Indochinese boat people studied 3 hours a day (Caplan, Whitmore, & Choy, 1989). American high school students in general study an average of 1½ hours a day. (Black eighth-grade children in Detroit study, on average, 2 hours *per week* [Oyserman, Bybee, & Terry, 2006]. Of course, at least some of this failure to do homework can probably be attributed to a school milieu that does not expect much.)

There is also no mystery about why Asian and Asian American children work harder. Asians do not need to read this chapter to find out that intelligence and intellectual accomplishment are highly malleable. Confucius set matters straight on this 2,500 years ago. He distinguished

between two sources of ability, one by nature—a “gift from Heaven”—and one by dint of hard work.

Asians today still believe that intellectual accomplishment—at any rate, doing well in math in school—is primarily a matter of hard work, whereas European Americans are more likely to believe it is mostly a matter of innate ability or having a good teacher (Chen & Stevenson, 1995; Choi & Markus, 1998; Choi, Nisbett, & Norenzayan, 1999; Holloway, 1988; Stevenson et al., 1990). Attitudes of Asian Americans on this topic are in between those of East Asians and European Americans.

Asians and Asian Americans have another motivational advantage over Westerners and European Americans. When they do badly at something, they respond by working harder at it. Heine and his colleagues (2001) brought Japanese and Canadian college students to a laboratory and had them work on creativity tests. The researchers randomly told some of the participants that they had done very well, and told others they had done rather badly. The investigators then gave the participants another creativity test and told them to spend as much time as they wanted on it. The Canadians worked longer on the creativity test if they had succeeded on the first one than if they had done badly, but the Japanese worked more on the creativity test if they had failed on the first one than if they had succeeded. If at first you don't succeed, try again harder—if you have a strong work ethic and you think that working harder will make you smarter.

Another undoubtedly important reason for Asians making the most of their natural intelligence is that their culture—as channeled to them by their families—demands it. In the case of Chinese culture, the emphasis on academic achievement has been present for more than 2,000 years. A bright Chinese boy who worked hard and did well on the Mandarin exams could expect to elevate himself to a high government position, which was well paid. This brought honor and wealth to his family and his entire village—and the hopes and expectations of his family and fellow villagers were what made him do the work. There was substantial upward mobility via education in China a couple of millennia before this was the case in the West.

Asian families are more successful in getting their children to achieve academically in part because Asian families are more powerful agents of influence than American families—and what they choose to emphasize is academic achievement.

The greater academic achievement of Asian Americans is a setup for social dissension of a kind we are already beginning to see. For example, non-Asians are complaining about higher admission rates to universities for Asians (representation of Asians at Harvard exceeds representation in the population as a whole by a factor of about 4). Meanwhile, Asians are complaining that their admission rates are not high enough; Harvard is currently being sued by Asian Americans for admitting non-Asian students with worse academic credentials than Asians who were rejected. The cultural capital advantage of Asians will probably be reduced as Asians assimilate more and more to popular culture norms (Flynn, 2007), but meanwhile the conflicts are probably going to get worse before they get better.

The good news is that the gap separating average African Americans' and Hispanics' cognitive skills from European Americans' skills is shrinking. I don't think it's overly optimistic to guess that conflicts over affirmative action in college admission for these groups is going to lessen substantially and perhaps even quite rapidly.

JEWISH–NON-JEWISH DIFFERENCES IN IQ

Jewish IQs have been estimated to be 7–15 points higher than those of white non-Jews in Britain and America (Flynn, 1991; Lynn, 2004, 2006), but all available studies are based on samples of convenience. (I am unaware of any data for Sephardic Jews. “Jews” should be taken here to mean “Ashkenazi Jews of European descent.”)

For centuries, Jews have been viewed as intellectually superior. In both Europe and the United States, there are some remarkable achievement differences between Jews and non-Jews. Jews are educationally and economically far more successful than the population at large (Burstein, 2007). There are numerous biological explanations for Jewish intellectual and economic success. None of these is supported well enough to be worth reporting here. It seems important that Jews were the first ethnic group (by about 2,000 years) to achieve literacy for all adult males. A Jewish tradition of scholarship developed that no other ethnic group in the West approached

for centuries. This could, of course, be regarded as due to genetic factors, but there is no compelling reason to assume that.

Even at the highest available estimates of Jewish IQ, it should be noted that Jewish accomplishment exceeds what would be predicted on the basis of IQ alone. The numbers of Ivy Leaguers, professors at elite colleges, Supreme Court clerks, and Nobel Prize winners are greater than we would expect even if average Jewish IQ were 115. But it is important to note that as remarkable as the superior achievement of Jews is, it is far less extreme in comparison to non-Jews than that of many other comparisons that cannot be explained on purely genetic grounds (e.g., Italians vs. English in the 15th century and English vs. Italians after the 18th century; Arabs vs. Europeans in the eighth century and Europeans vs. Arabs after the 14th century, and New Englanders vs. Southerners throughout American history).

CULTURE AND CREATIVITY

Up to this point, I've been writing as if IQ as measured in contemporary tests is the sole or even primary criterion of intelligence. But I don't believe this, for many reasons. Heuristics and algorithms of a wide variety of types, which I have called pragmatic reasoning schemas, are part of what comprise intelligence. These include heuristics discussed earlier (e.g., statistical, methodological, psychological, and economic). Such schemas are crucial for myriad types of problems in the modern world, and these are not measured by IQ tests—though they should be and will be in the future.

Also, we know that intellectual achievement is affected by several attributes that are not well captured by current IQ tests. These include creativity and practical reasoning, which Robert Sternberg (1999) has shown to be only weakly correlated with IQ and to predict both academic achievement and occupational achievement over and above the level of prediction achieved by IQ score.

By stereotype, there are cultural differences in creativity. It's a common view among American academics that East Asians are less creative than Europeans or Americans. It's believed that they come to graduate school well versed in the necessary facts and procedures but without the cognitive tools necessary for discovery. A telling fact that is consistent with this stereotype

is that exams in Korea, even those in higher education, are exclusively multiple-choice. The implication may be that education is about learning facts, as opposed to how to reason, how to generate hypotheses, and how to evaluate ideas. This lesson is reinforced by the fact that discussion classes are rare in Asian classrooms. Asian graduate students in American universities can sometimes seem a little bewildered by discussion in class—as if they do not have a clear idea of what is the purpose is. (But let's be frank: There often isn't any clear purpose being served!)

There is universal agreement among social scientists that Westerners are more individualistic than Easterners, and that a part of individualism is the value placed on distinctiveness and originality. There is some evidence from empirical research that Westerners are in fact more original in their thinking (Mok & Morris, 2010). Westerners have been found to outperform East Asians on a variety of tests of divergent thinking, producing a higher proportion of novel responses to questions of various kinds (Chandrasekaran & Tellis, 2008; Jaquish & Ripple, 1984; Jellen & Urban, 1989; Leung, Au, & Leung, 2004; Lynn, 2006; Ng, 2001; Niu & Sternberg, 2001; Zha, Walczyk, Griffith-Ross, Tobacyk, & Walczyk, 2006). Consistent with these results, priming individualism heightens divergent thinking, whereas priming collectivism diminishes it (Goncalo & Staw, 2006).

It should be noted that some studies of cultural differences rely exclusively on Western-devised tests, Asian participants are sometimes tested in English, and some studies fail to find cultural differences (Chiu & Hong, [Chapter 26](#), this volume; Saiki, Fan, & Dusen, 2001). And it has to be noted that the range of tests of creativity is fairly restricted. However, the hypothesis of greater Western creativity has yet to be convincingly contradicted, and it fits a great deal of what we know about differences between Easterners and Westerners.

A mea culpa is in order here. Fifteen years ago, I pointed out in *The Geography of Thought* (2003) that despite the fact that Japan spends a great deal on scientific research, there was only one Japanese Nobel Prize in science in the 1990s (compared to 44 for Americans). I attributed this to relatively lower creativity (and curiosity) on the part of Japanese. Since 2000, 16 Nobel Prizes in science have been awarded to Japanese individuals, far more than were awarded during that period to the British, French, or Germans. Remarkable success for people lacking in creativity and curiosity!

I am now wisely refraining from predicting what the success of Chinese and Koreans will be in science.

REASONING STYLES OF THE WEIRD AND THE NON-WEIRD: ANALYTIC VERSUS HOLISTIC REASONING

Masuda, Russell, Li, and Lee ([Chapter 8](#), this volume) review evidence showing that Westerners, or perhaps I should say WEIRD people (Western, Educated, Industrialized, Rich, Democratic), are biased toward analytic reasoning, whereas Easterners, or perhaps I should say non-WEIRD people, are biased toward holistic reasoning. Analytic reasoning is characterized by attention to the attributes of objects, organizing the world via categories and rules pertaining to those categories, and applying formal logic to everyday problem content. Holistic reasoning is characterized by broad attention to the physical, social, and temporal context, organization of the world via relationships and similarities, and the application of a dialectical approach to everyday problem content. Kaiping Peng and I, and our collaborators, have defined “dialecticism” as a tendency to attend to context, to avoid separating form from content, to attend to relationships between objects and between people, to assume that conflicting propositions may both be good representations of the world, to avoid black and white, either–or distinctions, to expect change in events and processes, to anticipate cyclical rather than linear change, and to avoid dogmatic certainties (de Oliveira & Nisbett, 2017; Nisbett, 2003; Nisbett, Peng, Choi, & Norenzayan, 2001; Peng & Nisbett, 1999; Peng, Spencer-Rodgers, & Nian, 2006).

These cognitive biases and heuristics can be thought of as skills. This is particularly obvious for analytic biases. It’s useful to be able to attend carefully to attributes of objects, to think of them in terms of categories and the rules that apply to the categories, and to apply formal models, including logic, to concrete problems. Indeed, this cognitive stance is necessary for scientific thought. On the other hand, there is a less useful aspect to each of these cognitive biases. An exclusive focus on objects can result in the “fundamental attribution error”—the tendency to wrongly ignore the role of the context or situation in attempts to understand the behavior of objects

and people. Emphasis on categorization can lead to stereotyped thinking and ignoring the distinctive properties of the object being categorized. Formalisms always involve stripping away details, and the details may be essential to solving a problem correctly.

Holistic thought has its own virtues and other-side-of-the-coin vices. Attending to context is almost always useful, as is noting relationships and similarities. It's only when these tendencies preempt a necessity to attend closely to objects, and the categories and rules that apply to the attributes of objects, that the tendencies can lead to error.

The package of skills and stances that constitute a dialectical approach to the world are all likely to be useful when applied heuristically. Refusal to separate form from content is perhaps usually a good idea—except when such separation prevents accessing useful formalisms. Black and white characterizations are perhaps in general best avoided, though it can sometimes be useful to insist on rigid distinctions. The belief that opposing propositions can both contain truth is a useful heuristic, though an insistence on this stance can lead to the error of assigning too much plausibility to weakly supported propositions (Peng & Nisbett, 1999). Presuming that change is likely is probably normally useful, except when there is justification for assuming stasis. The presumption of cyclical change can be helpful in many ways, for instance in recognizing events that are subject to statistical regression, though, again, that presumption can lead to erroneous conclusions: When the world is static or moving monotonically, it can be disastrous to assume curvilinearity or cyclical change (Ji, Su, & Nisbett, 2001; Ji, Zhang, & Guo, 2008).

Grossman, Varnum, Karasawa, Kitayama, and Nisbett and their colleagues have argued that a dialectical stance is likely to lead to wise solutions of social problems, especially when the problems are caused by conflicting purposes or needs (Grossmann et al., 2010, 2012; Grossman & Kung, [Chapter 13](#), this volume). Grossman and his colleagues (2012) have shown that younger Japanese are wiser in their analysis of social conflict than younger Americans, which is what would be expected if Japanese cognitive socialization is substantially biased toward dialectical reasoning. On the other hand, Japanese do not become wiser as they age, whereas Americans do (Grossman et al., 2012). It seems likely that Americans become wiser about social conflict because their frequent encounters with it

prompt induction of principles resembling dialectical approaches, which enable them to deal with it effectively.

Formal education in the Western tradition undoubtedly serves to strengthen cultural tendencies toward analytic reasoning. There's little doubt that when non-Western (non-WEIRD) people are exposed to Western-style education, analytic tools of thought are readily learned. I have preliminary data indicating that young middle-class Chinese Americans who have lived at least 10 years in Silicon Valley are indistinguishable from European Americans.

I am insufficiently familiar with formal education in the Eastern tradition to know whether it serves to strengthen tendencies toward holistic thinking. In any case, I suspect that teaching the virtues of holistic reasoning is going to be a much more difficult matter than teaching analytic reasoning. Analytic reasoning consists largely of easily learned rules. Holistic thinking is deeply rooted in socioemotional enculturation practices that begin at a very early age.

SOME CONCLUSIONS

The concept of a culture-free IQ test is oxymoronic. IQ is culturally defined and culturally achieved. (Although, however defined and achieved, intelligence is undoubtedly genetically influenced.)

Different cultures require different intelligences. What we think of as IQ at the moment is a snapshot in time and place. Though the tests remain the same, people's scores have not. They continue to increase—the more developed the country, the less rapidly. The causes of the increase in IQ include increased education and culture shifts that place increased demands on intellectual skills.

The Industrial Revolution accidentally resulted in improved cognition across many dimensions, including abstraction, formal logic, counterfactual reasoning, and hypothesis testing. Once these skills began to develop, and their relevance to occupational success was recognized, they began to be assessed by IQ tests. The Information Revolution requires many additional cognitive practices and skills, including heuristics based on statistical methods, economic and psychological concepts, and scientific methodology.

These heuristics (which become algorithms in some formal contexts) are not currently thought of as IQ-type abilities. But they will be thought of this way in the not-too-distant future, and the knowledge and skills assessed by IQ tests will change markedly. The more developed the country, the sooner these changes, and the tests intended to measure them, will occur.

Meanwhile, different groups within a given society are socializing for different kinds of intelligence. Middle-class people socialize for the skills needed for people in professional, technical, and managerial fields. Lower-SES people socialize for jobs requiring a lower level of expertise. Some ethnic groups make heavy demands on their children to learn the higher-level skills and others make relatively few demands. Consequent differences in cognitive skills between Asians and non-Asians are going to be a continuing source of social conflict for the foreseeable future.

Individuals and groups differ in cognitive orientations that contribute to intellectual achievement but are not measured by IQ tests. These orientations include practical intelligence and creativity. Cultures differ in other cognitive attributes that can be regarded as abilities. Analytic skills, more developed in the West, are readily taught to non-Westerners. Holistic, dialectical approaches, more developed in the East, may prove to be difficult to teach.

ACKNOWLEDGMENTS

CHAPTER 8

Cognition and Perception

**Takahiko Masuda, Matthew J. Russell, Liman
Man Wai Li, and Hajin Lee**

This chapter reviews key empirical findings related to cultural variations in cognition and perception. First, we introduce current discourses in cultural psychology in terms of the origins of cultural variations in cognition and perception by discussing a chain of influences on cognition and perception by environments, cultural practices, and cultural discourses. Next, we introduce empirical studies that have demonstrated substantial cultural variations in cognition and perception. We introduce key findings on person perception, social attention, and naive dialecticism. In addition, we introduce findings related to their developmental and neural bases. Finally, we propose five future topics to further advance research on cultural variation in cognition and perception: moving beyond the East–West dichotomy, other sources of cognition and perception, cultural learning, cultural neuroscience, and individual versus cultural-level phenomena.

For more than a quarter of a century, cultural psychologists have advanced various theoretical frameworks for understanding human behaviors in sociocultural contexts (e.g., Bruner, 1990; Markus & Kitayama, 1991, 2010; Miller, 1999; Shweder, 1991). This work can be traced back to Wilhelm Wundt's (1916) *völkerpsychologie* (folk psychology), as well as to discourses in other disciplines, including anthropology (e.g., Geertz, 1973; Kluckhohn, 1944), sociology (e.g., Garfinkel, 1985), linguistics (e.g., Sapir, 1983; Whorf, 1956), and comparative behavioral science (e.g., Mesoudi, 2011; Richerson & Boyd, 2005; Tomasello, 1999). Furthermore, scholars in developmental psychology (e.g., Cole, 1996; Luria, 1976; Rogoff, 2003; Vygotsky,

1930/1978), social psychology (e.g., Sherif, 1936), educational psychology (e.g., Stevenson & Stigler, 1992), and some schools of cognitive psychology (e.g., Medin, Ojalehto, Waxman, & Bang, 2015) have helped develop the foundations of cultural theories. Finally, as we discuss throughout this chapter, neuroscience methods have become increasingly common (e.g., Chiao, 2009; Han et al., 2013; Kitayama & Tompson, 2010; Kitayama & Uskul, 2011; see Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume).

One prominent theoretical approach in this body of work is that people in different cultures have different ways of viewing themselves and the world; moreover, these different views of the self and the world are associated with culture-specific patterns of cognition and perception. For example, Markus and Kitayama (1991, 2010) contrasted two social orientation models: *independent* and *interdependent*. Those who live in a culture where *independent social orientation* is dominant tend to view themselves as separated from social others, and hold cognitive styles that emphasize self-direction, autonomy, and self-expression, whereas those who live in a culture where *interdependent social orientation* is dominant tend to view themselves as socially interrelated and connected to significant relationships, and hold cognitive styles that emphasize harmony, relatedness, and connection. Also, research by Nisbett and colleagues (Nisbett, 2003; Nisbett, Peng, Choi, & Norenzayan, 2001) contrasted two kinds of thinking styles: *analytic* and *holistic/dialectical*. The *analytic thinking style* is characterized by an emphasis on an object-oriented focus in visual attention (selectively focusing more on objects than on context), taxonomic and rule-based categorization, dispositional orientation in causal attribution and social inference, and formal logic in reasoning. Conversely, the *holistic/dialectical thinking style* is characterized by an emphasis on a context-oriented focus of attention (attending to objects in relation to their context), thematic and family resemblance-based categorization of objects, situational orientation in causal attribution and social inference, and dialectical logic in reasoning.

This chapter reviews key empirical findings regarding these social orientations and thinking styles, with a focus on comparisons between Western and East Asian cultures. First, we introduce some current discourses in cultural psychology that help elucidate the origins of cultural variations in cognition and perception (e.g., Kitayama & Uskul, 2011;

Miyamoto, 2013; Nisbett, 2003; Varnum, Grossmann, Kitayama, & Nisbett, 2010). We then discuss empirical studies that have demonstrated substantial cultural variations in cognition and perception. Finally, we propose future directions for research on how culture influences cognition and perception.

THE ORIGIN OF CULTURAL VARIATIONS IN COGNITION AND PERCEPTION

What types of experience influence our cognition and perception? One major point of view in cultural psychology holds that environment (i.e., natural ecology and social environment) has an important influence on cultural variations in cognition and perception. In early studies, researchers demonstrated that experiences afforded by *ecology* directly influence perceptual illusions. For example, the “carpenter hypothesis” argues that familiarity with the configuration of corners in buildings facilitates the magnitude of the Müller–Lyer optical illusion (e.g., Cole & Scribner, 1974, for a review, see Gregory, 1968; McCauley & Henrich, 2006; Miyamoto, Nisbett, & Masuda, 2006; for a contemporary replication of this idea, see Rivers, 1901, 1905; Segall, Campbell, & Herskovits, 1966). Recent researchers have further advanced this perspective by pointing out that ecology can also influence cognition and perception indirectly by changing social structure and cultural practices (Kitayama & Uskul, 2011; Nisbett, 2003; Nisbett et al., 2001; Peng & Nisbett, 1999; Varnum et al., 2010). In this section, we review the frameworks and empirical evidence related to these influences.

Subsistence Systems and Cultural Practices

Early cross-cultural studies led by Berry, Witkin, and their colleagues demonstrated that subsistence systems (e.g., hunting gathering, herding, fishing, and farming) and associated cultural practices (e.g., the lifestyle necessary for sustaining a given economic subsistence system) influence our cognition and perception (e.g., Berry, 1966, 1971; Dowson, 1967; Witkin, 1967; Witkin & Berry, 1975; Witkin, Dyk, Faterson, Goodenough, & Karp,

1974; Witkin & Goodenough, 1977; Witkin et al., 1954). For example, evidence was found that hunters in Canadian First Nations communities, who have fewer strict rules regarding social relations, are better at perceiving objects independently from each other, compared to rice farmers in Temne communities in West Africa, where communal works are more emphasized (Berry, 1966; Witkin & Berry, 1975). Another study showed similar contrasts between Bagandu farmers and Biaka pygmy hunter-gatherers in the Central African Republic (Berry et al., 1986; see Talhelm & Oishi, [Chapter 4](#), this volume).

One way theoretically to understand these earlier findings is to hypothesize that ecology influences social orientation, which in turn influences cognition and perception (Talhelm et al., 2014; Uskul, Kitayama, & Nisbett, 2008; Varnum et al., 2010); that is, an interdependent social orientation and a more holistic cognitive style may develop when ecology fosters social cooperation, as is seen when ecology forges labor-intensive farming (e.g., rice farming), whereas an independent social orientation and a more analytic cognitive style may develop when ecology encourages less social or more solitary activities such as herding.

To seek support for these ideas, Uskul et al. (2008) tested three communities in the Black Sea region of Turkey, where people are ethnically similar and speak the same language but differ in their primary economic activities and subsistence systems. They found that herders, who often work alone, tend to hold a more independent social orientation and analytic thinking style, whereas farmers and fishers, whose cooperative works are both valued and required, tend to hold a more interdependent social orientation and holistic thinking style. Furthermore, Talhelm et al. (2014) found evidence that residents of areas traditionally linked to rice farming (vs. wheat farming) in China show contrasting cultural patterns, with those from regions historically associated with rice farming showing an interdependent social orientation and holistic thinking, and regions historically associated with wheat farming showing an independent social orientation and analytic thinking. Talhelm et al. maintained that rice farming, which requires cooperative work (e.g., maintaining irrigation systems), leads people to hold interdependent mentalities and to pay attention to contexts. In contrast, wheat farming relies on natural rainfall

and requires less cooperative work, leading to a more independent social orientation and less attention to context.

Related to the pairing of social orientation and thinking styles, research suggests that social orientation may cause thinking style differences, with the priming of social orientation styles resulting in thinking style changes (e.g., Oyserman, 2015; Varnum et al., 2010). After receiving independent primes, individuals show a more analytic thinking style, and after receiving interdependent primes, individuals take on a more holistic thinking style.

Cultural Discourses

While ecological environments may lead to the establishment of subsistence systems and practices that address the needs of these systems, cultural discourses (stories and narratives people develop to make sense of the world) are also important to the continued use of these practices. On the one hand, people in independent cultures develop discourses that emphasize self-direction, autonomy, and self-expression. On the other hand, people in interdependent cultures develop discourses that emphasize harmony, relatedness, and connectedness (Kitayama, Ishii, Imada, Takemura, & Ramaswamy, 2006; Kitayama, Mesquita, & Karasawa, 2006; Varnum et al., 2010).

Nisbett and colleagues (Nisbett, 2003; Nisbett et al., 2001) discussed the emergence of holistic and analytic thinking styles through cultural discourses. As ancient Chinese were interdependent, they developed discourses about the world that supported a *holistic/dialectical thinking style*. For example, Taoist teachings focus on a holistic/dialectical view of the world, emphasizing that seemingly contradictory and opposing forces constantly alternate between and influence each other. Due to these alternations over time, Taoist teachings also emphasize that we should not be misled by a local state of events when understanding the complexity of the world. Similarly, Confucius's teachings focus on the complexity of relationships among people and our need to focus on these relationships instead of on individuals. As shown in these examples, the discourses of ancient China emphasized the complexity of relationships among people, society, and things. These discourses helped to solve issues in their historic

subsistence systems by emphasizing the need for compromise and the ever-important value of social harmony.

In contrast, ancient Greeks lived in a mountainous ecology. They established their civilization while relying on subsistence systems that involved hunting, fishing, herding, and trading. People needed to negotiate and debate with others as independent agents, rather than seek harmony and compromise. Influenced by such subsistence systems and associated cultural practices, the ancient Greeks developed different discourses about the world. For example, ancient Greek philosophy emphasized the notion that the world is fundamentally static and unchanging, with Aristotle's concept of "essence" based on the unchanging attributes of objects. As shown in these examples, these discourses emphasized the importance of relying on an *analytic thinking style* by highlighting the predictability of the world and the idea that an object has discrete characteristics that are defined by internal attributes.

The Continuation of Cultural Practices and Discourses

Once cultural practices and discourses have been well established in a given culture, they can then act as culturally inherited knowledge. In this way, such shared cultural discourses sustain themselves, can spread to other regions of the world, and persist even when there no longer exist the initial ecological conditions that were instrumental in developing them (see Mesoudi, [Chapter 5](#), this volume; Ishii, Miyamoto, Rule, & Toriyama, 2014; Masuda & Yamagishi, 2010).

There is evidence that historically divergent cultural practices and discourses weather time and create variations in individual's cognition and perception, and within countries. Researchers who have targeted regional differences in cultural ideas in Italy have discussed how Northern Italy was historically influenced by a political system originating from medieval guild systems that emphasized a horizontal social structure (e.g., egalitarian social structure) and independence. In contrast, southern Italy was influenced by the feudal systems of the Norman kingdom, which emphasized a vertical social structure (e.g., power-oriented hierarchical social structure) and interdependence (Knight & Nisbett, 2007; Martella & Maass, 2000; Putnam,

Leonardi, & Nanetti, 1993). Although these systems have ceased to exist, studies have demonstrated that contemporary southern Italians are still more likely than their northern Italian counterparts to demonstrate holistic cognitive habits.

There also is evidence that cultural practices and discourses radically spread to new regions of the world and are sustained. For example, Aristotle's influence on Western philosophy is one such example. Although Aristotle's theory originated in Greece, his ideas were transmitted to Arab cultures and later flourished in European cultures (Nisbett, 2003). Similarly, Nisbett and Cohen (1996) maintained that there is a clear relationship between the immigrant Celtic/Scots herding heritage and the "culture of honor" in the U.S. South (e.g., maintaining one's reputation by not accepting insults from others). Although the historic subsistence system no longer exists, people in the U.S. South still sustain the culture of honor.

Socially shared cultural discourses, such as religious beliefs, also have been shown to transmit across regions and influence cognition and perception of the members of the specific religious environment: Migrants hold on to their preexisting beliefs and continue their religious activities, such as when different denominations of Christianity spread over to North America as immigrants moved from their original European nations. For example, we can contrast Calvinism/Protestantism and Catholicism, which has carried on over generations and across geographical regions. Calvinism/Protestantism emphasizes the importance of contemplating the inner state of the individual's soul rather than one's relationships with others. Calvinism/Protestantism also emphasizes individual responsibilities, similar to the independent social orientation, whereas Catholicism emphasizes social responsibilities, similar to the interdependent social orientation. As would be expected under the social orientation hypothesis, people in the regions where Calvinism/Protestantism was spread show more analytic tendencies in their cognitive styles than people in the regions where Catholicism is spread, who are more holistic (Colzato et al., 2010; Y. Li et al., 2012; Sanchez-Burks, 2002; Varnum et al., 2010).

Together, these findings give evidence that people have the ability to maintain cultural practices and discourses across time and place. As suggested before, such practices and discourses do not appear out of nowhere. Many originate in subsistence systems, but once cultures are

established in a given cultural context, they become somewhat independent of those antecedents.

Summary

We have described in this section how environment influences cultural practices and discourses, and these cultural practices and discourses relate to cognition and perception (e.g., Markus & Kitayama, 1991, 2010; Nisbett, 2003; Nisbett et al., 2001; Varnum et al., 2010). We have also described how such cultural practices and discourses are sustained even in the absence of the original subsistence systems. In the next section, we introduce cross-cultural findings involving how practices and discourses influence cognitive and perceptual phenomena, focusing on social judgments, holistic thinking, and dialectical thinking.

CULTURE, COGNITION, AND PERCEPTION

Cultural Variations in Person Perception

According to the social orientation account of culture, we would expect to find substantial differences in social judgments between people in cultures where independent social orientations are dominant and those in cultures where interdependent social orientations are dominant. Indeed, research has shown that East Asians tend to report more variation in their behaviors across social contexts, and North Americans tend to report more consistency across social contexts (e.g., Church et al., 2012; Hamamura, Heine, & Paulhus, 2008; Kanagawa, Cross, & Markus, 2001; Kashima et al., 2004). Furthermore, such social differences also generalize to how people interpret others' behaviors (Kashima, Siegal, Tanaka, & Kashima, 1992) and attend to social context (e.g., Masuda et al., 2008b). We introduce in this section the finding that culture influences social judgments affecting causal attribution, spontaneous social inferences, and emotion judgments.

Causal Attribution

One major area of research in social judgment concerns how people interpret and explain causes of social events. There are two ways we can attribute the causes of social events: (1) internally, attributing causes to internal factors such as the person's dispositions or attributes; and (2) externally, attributing causes to external factors such as social structure, physical constraints, or group pressures. Early research suggested that people tend to infer others' dispositions from their behaviors (internal attribution), even when the situation clearly imposes external constraints (Jones & Harris, 1967). This phenomenon was referred to as "correspondence bias" (Jones, 1979) or "fundamental attribution error" (Ross, 1977). Various researchers have reported that the bias was robust among North Americans even when situational constraints were made salient (e.g., Gilbert & Jones, 1986; Gilbert & Malone, 1995; Jones, 1979; Snyder & Jones, 1974; Uleman, Newman, & Moskowitz, 1996).

Subsequent research has investigated the effect of culture on correspondence bias. The findings indicated that North Americans (i.e., Americans) tended to show more correspondence bias than East Asians (i.e., Koreans) when contextual information was made apparent (Choi & Nisbett, 1998); and that when asked to predict people's behaviors, East Asians were more likely than Americans to take situational factors into account (Norenzayan, Choi, & Nisbett, 2002). Other attribution research has produced similar findings (e.g., F. Lee, Hallahan, & Herzog, 1996; Morris & Peng, 1994). For example, Morris and Peng asked Chinese and Americans to first watch animated vignettes of ball movements (a nonsocial condition) and groups of fish (a social condition), then to provide reasons for the movements of the target objects (either ball or fish). They found that Chinese tended to explain the fish movements by referring to external factors (e.g., the influence of other fish), whereas Americans tended to refer to internal factors (e.g., the intention of the target fish). In a similar study, when participants were asked to give possible reasons for why a student killed his professor, Chinese were more likely than Americans to refer to external factors such as situational constraints and pressures (Morris & Peng, 1994).

Researchers have also examined when cultural variations in internal and external attributions emerge in youth and young adults in Hindu (interdependent) and American (independent) cultures. Miller (1984) found

that the culturally dominant patterns gradually increased with age, with cultural differences becoming significant around the age of 15 (see also Monga & John, 2007). These findings suggest that cultural differences in attributions take time to develop, stabilizing in adolescence.

Spontaneous Social Inference

Several researchers have posited that the correspondence bias involves spontaneous, automatic processes (e.g., Gilbert & Malone, 1995; Newman, 1993; Uleman et al., 1996). According to Gilbert and Malone (1995), social inferences consist of two processes: (1) initial automatic dispositional inferences and (2) subsequent adjustments of those inferences, possibly taking situational factors into account. Gilbert, Pelham, and Krull (1988) argued that although corrections are possible, automatic dispositional inferences stabilize attributions early, making later adjustments difficult. Researchers looking for this initial, automatic correspondence bias (called “spontaneous trait inference”) have found evidence of its presence (see Uleman, Adil Saribay, & Gonzales, 2008, for a review). For instance, when North American participants read a description of a person’s behavior (e.g., the person solved a mystery fast), they tended to spontaneously assign traits to this person (e.g., that the person was “clever”). However, accumulating evidence also suggests that culture affects the occurrence of this spontaneous trait inference (e.g., H. Lee, Shimizu, & Uleman, 2015; Na & Kitayama, 2011; Newman, 1991; Shimizu, Lee, & Uleman, 2017; Zárate, Uleman, & Voils, 2001), with people from independent cultures showing stronger tendencies to make spontaneous trait inferences than do those from interdependent cultures.

These cultural differences in spontaneous trait inferences were also reflected in neural patterns related to the early processing of stimuli, called “event-related potentials” (ERPs). In Na and Kitayama’s (2011) study, European American and Asian American participants performed a lexical judgment task, in which participants were first asked to view people’s faces, paired with behavioral descriptions that implied traits. Then, to test whether they made spontaneous trait inferences, the participants were given another task, in which the previously paired faces were paired with inferable traits or

antonyms of these inferable words from the original face–behavior pair. During this second task, the researchers measured the participants’ N400 ERPs, which reflect the early detection of semantic incongruity; stronger N400 ERPs occur when information is considered incongruent. Based on previous research, if the participants made a spontaneous trait inference, we could expect a stronger N400 in response to the antonyms than to the implied traits, showing that the antonym was unexpected (e.g., Kutas & Federmeier, 2011).

Na and Kitayama (2011) found that only European Americans showed this N400 pattern, suggesting a spontaneous trait inference, whereas Asian Americans did not. Furthermore, social orientation beliefs mediated these N400 patterns, with more independent individuals showing stronger N400-related spontaneous trait inferences. This is an important finding, as it lends validity to the notion that social orientation differences drive the spontaneous trait inference. Conceptually replicating these findings, evidence comparing middle- and working-class individuals further supports the notion that social orientation differences are key to how people make spontaneous trait inferences (e.g., Grossmann & Varnum, 2011; Varnum, Na, Murata, & Kitayama, 2012). Working-class individuals, who have been shown to be more interdependent, showed no difference in the N400 between conditions, suggesting no spontaneous trait inference, whereas middle-class individuals, who have been shown to be more independent, did exhibit such a difference (Grossmann & Varnum, 2011; Kraus, Piff, & Keltner, 2009; Varnum et al., 2012).

Cultural Variation in Inference Type

Researchers have also examined cultural variation in the type of inference made. For example, one line of research targeted how cultural variation in the perception of agency affects inferences (Chiu, Morris, Hong, & Menon, 2000; Menon, Morris, Chiu, & Hong, 1999). Due to noted social orientation differences, the researchers hypothesized that East Asians would perceive the group as a coherent agentic unit, whereas North Americans would perceive the group as a sum of individual agents. In line with this reasoning, Menon et al. (1999) found that East Asians made more trait inferences

related to the group, while North Americans made more trait inferences related to individuals. Another line of research investigated cultural variation in the type of information spontaneously inferred (e.g., Ham & Vonk, 2003; H. Lee, Shimizu, Masuda, & Uleman, 2017b; Lupfer, Clark, & Hutcherson, 1990; Todd, Molden, Ham, & Vonk, 2011). H. Lee et al. (2017b) compared the extent to which trait and situational information is spontaneously inferred. In line with noted social orientation and thinking style differences, they found that Japanese tend to infer background situational information as much as trait information, whereas North Americans tend to predominantly infer trait information.

Emotion Judgments

Research on the cognition and perception of facial expressions is an important topic of investigation in psychology (e.g., Ekman, 1971; Ekman & Friesen, 1971; Ekman, Friesen, & Ellsworth, 1972; Izard, 1971, 1994). Related to this topic, recent research has regularly compared East Asian and North American participants' attention to emotions (Ito, Masuda, & Li, 2013; Ko, Lee, Yoon, Kwon, & Mather, 2011; Masuda, Wang, Ishii, & Ito, 2012; Matsumoto, Kwang, & Yamada, 2010; Miyamoto, Yoshikawa, & Kitayama, 2011; Stanley, Zhang, Fung, & Isaacowitz, 2013). For example, Miyamoto et al. (2011) demonstrated that holistic thinkers apply a configural-oriented mode of attention (e.g., viewing the face as a whole, being sensitive to the relationship among facial parts), and analytic thinkers apply a feature-oriented mode of attention (e.g., attending to each facial feature). In addition, research has documented that when asked to perceive faces, Westerners selectively attended to specific parts of the face (e.g., eyes and mouth), whereas East Asians attend to the eye area or the center of the face (Blais, Jack, Scheepers, Fiset, & Caldara, 2008; Jack, 2013; Jack, Blais, Scheepers, Schyns, & Caldara, 2009; Jack, Garrod, Yu, Caldara, & Schyns, 2012; Yuki, Maddux, & Masuda, 2007). It is possible that East Asians use this configural strategy to see various parts of the face by placing their gaze on a central area, while North Americans switch their attention more among areas, allowing them to parse through features.

Similarly, research has documented that these cultural differences also affect how people view individuals' emotions, either taking social context into account or not doing so. Masuda and colleagues (2012; Masuda et al., 2008b) used face lineups to examine the emotion context sensitivity of North Americans and East Asians. The center person was flanked by two people who both showed an emotion that was either the same as or different from that of the center person, and participants were asked to judge the center person's intensity of emotion. This researchers found that East Asians were more likely than North Americans to take the background people's emotions into account and to adjust their ratings of the center person's emotions accordingly. The participants' eye movement patterns were also consistent with this cultural difference in social attention, with East Asians paying more attention to background faces. These results support the idea that cultural differences in social orientation and thinking styles also affect how people perceive emotions; those from more interdependent cultures tend to see people's emotions as embedded in the social context, and those from more independent cultures tend to regard people as free from this social context. In terms of the lifespan development of these patterns, H. Lee et al. (2017a) found that cultural patterns for the face lineup task were not observable by 7- to 9-year-olds, but emerged around age 10. Masuda et al. speculated that this occurs during this time period due to the development of key language skills and a more advanced understanding of interpersonal relationships.

These cultural differences in how people attend to emotions also affect early attention to emotional content, as seen through ERPs. Russell, Masuda, Hioki, and Singhal (2015) investigated ERP patterns when European Canadians and Japanese viewed the previously described face lineups (Masuda et al., 2008b; Masuda et al., 2012). Russell et al. (2015) targeted the N400 ERP, as the N400 has been related to the detection of semantic incongruities (e.g., Kutas & Federmeier, 2011). Stronger N400s might be expected for lineups with differing emotions between the center and background people (more so than for similar emotions) when such a pattern was considered problematic to people's worldviews (i.e., if they were worried about social harmony). According to social orientation theory, we could expect this pattern for interdependent (vs. independent) cultures. Consistent with this prediction, the results indicated that only Japanese showed

stronger N400 ERPs in response to differences between central and background emotions (vs. similar emotions), suggesting that interdependent social orientations also lead to additional early neural processing of emotional incongruence (Figure 8.1). Using a similar paradigm, Fong et al. (2014) showed that priming bicultural Asian Americans with independence beliefs can remove this increased processing when central and surrounding faces show different emotions.

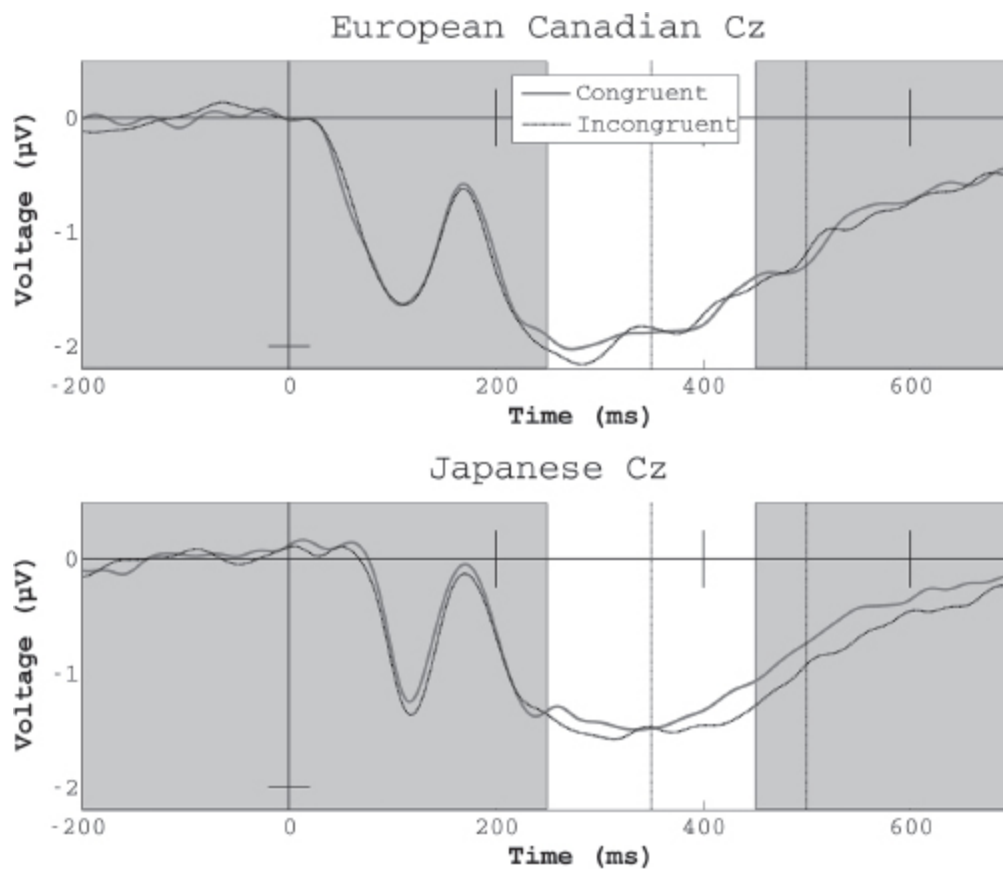

FIGURE 8.1. N400 waveforms for the face-lineup ERP study (Russell et al., 2015). Waveforms are shown for the similar emotions and *incongruent* different emotions conditions for European Canadians and Japanese. As the N400 is a negative deflection, a more negative waveform is taken as evidence of a stronger N400.

Aside from visual emotional influences, culture has also been shown to affect how people make judgments in emotional auditory tasks. For example, Ishii and colleagues demonstrated that when judging the valence of word meanings, Asians (both Japanese and Filipinos) tended to be affected

by the valence of the intonation, suggesting that they were biased to attend to auditory context. In contrast, North Americans tended to be affected by the meaning of words, even when they were told to ignore meaning and judge the valence of intonations, suggesting a selective attention to word meaning over auditory meaning (Ishii, Reyes, & Kitayama, 2003; Ishii & Kitayama, 2002; Kitayama & Ishii, 2002). This task has also been studied with ERP methods with Japanese, providing evidence that they are sensitive to the incongruence between the content of words and vocal tones. This sensitivity increased in response to the presence of schematic human faces, and was greater for females than for males (Ishii, Kobayashi, & Kitayama, 2010).

Cultural Variations in Attention to Events

We now discuss findings that indicate the effects of social orientation differences extend to nonsocial contexts, often discussed under the umbrella of analytic versus holistic thinking styles (Choi, Nisbett, & Norenzayan, 1999; Nisbett & Masuda, 2003; Nisbett & Miyamoto, 2005; Norenzayan & Nisbett, 2000). The influence of holistic versus analytic thinking styles on cognition and perception is vast, affecting a wide variety of domains, including abstract tasks (Ji, Peng, & Nisbett, 2000; Kitayama, Duffy, Kawamura, & Larsen, 2003; Stanley et al., 2013), attention to objects (Boduroğlu, Shah, & Nisbett, 2009; Doherty, Tsuji, & Phillips, 2008; Masuda, Akase, Radford, & Wang, 2008a; Savani & Markus, 2012), and object categorization (Ji, Zhang, & Nisbett, 2004; Norenzayan, Smith, Kim, & Nisbett, 2002). Furthermore, these differences develop throughout childhood (Imada, Carlson, & Itakura, 2013; Senzaki, Masuda, Takada, & Okada, 2016).

The Effect of Culture on Attention

These cultural differences affect various aspects of the attention stream, from narratives and memory to eye movements and neural patterns (e.g., Chua, Boland, & Nisbett, 2005; Goh, Tan, & Park, 2009; Masuda & Nisbett, 2001; Masuda, Russell, Chen, Hioki, & Caplan, 2014). For example, Masuda and

Nisbett (2001) asked European Americans and Japanese to describe animated vignettes of underwater scenes. To differentiate focal information from context, each vignette consisted of salient focal objects such as fish, along with background information. Comparing participants' narratives of the scenes, Masuda and Nisbett found cultural differences in how people described these scenes. European Americans tended to selectively refer more to the focal objects, whereas Japanese tended to describe both focal objects and contextual information. Senzaki et al. (2016) looked at these differences in children ages 4–9, and found no cultural variations when children engaged in the task alone. However, when parents and children jointly engaged in the task, cultural differences did emerge. Children's patterns mirrored those of their parents (i.e., analytic in Canadians and holistic in Japanese), and this effect was particularly strong for older children (ages 7–9). Senzaki et al. interpreted the pattern as indicative of scaffolding (cultural) processes at work in parent–child interactions (Wood, Bruner, & Ross, 1976). With their parents' help, older children begin to imitate the thinking styles held by mature members of their society (see [Figure 8.2](#)).

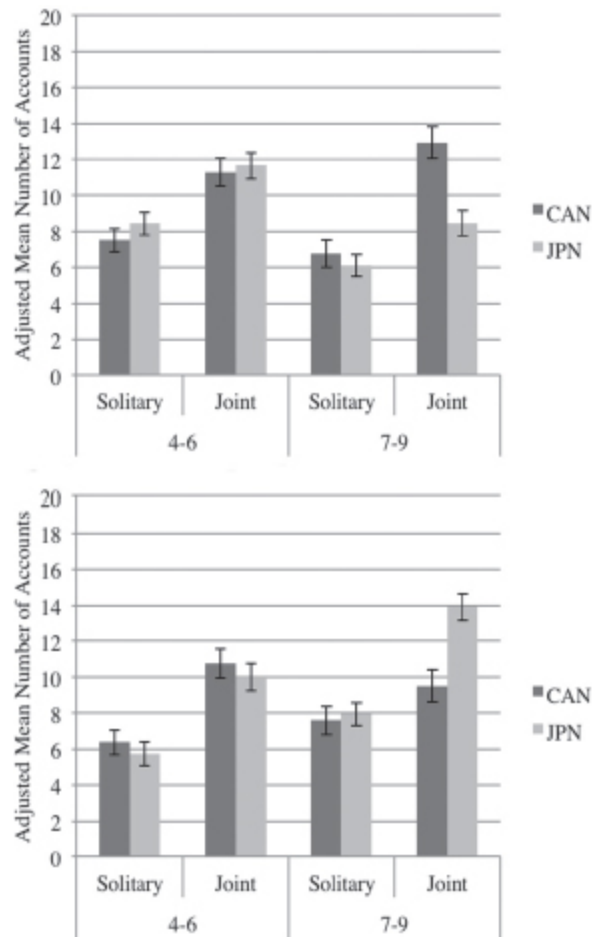

FIGURE 8.2. Results of the Senzaki et al. (2016) study. The mean number of foreground accounts (top) and background accounts (bottom) provided during children’s solitary and joint sessions, for 4- to 6-year old and 7- to 9-year-old Canadian and Japanese children.

Masuda and Nisbett (2001) further tested how cultural differences in attention influence memory by having European Americans and Japanese take part in an animal-wilderness recognition task. Participants were first asked to evaluate how much they liked animals that were placed in wilderness scenes. Later, in a surprise memory task, they were asked to make recognition judgments of these animals in four types of scenes: the same animals appearing in the same wilderness scenes as before (the *congruent condition*), the same animals in novel wilderness scenes (the *incongruent condition*), a novel animal in a wilderness scene shown before, or a novel animal in a novel wilderness scene. Masuda and Nisbett found differences between the congruent condition and the incongruent condition. Although groups for both cultures performed well when recognizing

congruent images, accuracy decreased for both groups when previously presented animals were paired with novel wildernesses. This effect was much more pronounced for Japanese than for Americans, suggesting that Japanese were more likely to holistically bind foregrounds and backgrounds during their processing of scenes than were Americans. A series of eye-tracking studies provided evidence that supported assertions about attention to both foreground and background (Chua et al., 2005; Senzaki, Masuda, & Ishii, 2014; Zhang & Seo, 2015). In one of these studies, Chinese international students were found to alternate their gaze more between foreground and background context during the initial rating part of the animal-wilderness task, while Americans focused more on foreground objects (Chua et al., 2005).

The Neuroscience of Attentional Differences

Neuroscience research conducted by Masuda et al. (2014) has provided further evidence for what may occur during this process. As in the Masuda and Nisbett (2001) study, after a learning phase in which subjects were provided a number of animals paired together with different wilderness contexts, they were given a recognition test. In this test, some of the previously presented (old) animals were paired with the old context with which they were initially paired, whereas other old animals were paired with a novel (new) context. Previous work using a similar procedure showed that new context presented in the recognition task elicits a stronger N400 ERP response than did old contexts, sometimes referred to as the FN400, a frontal, recognition memory type of the N400 (e.g., Tsvilis, Otten, & Rugg, 2001). Different from the semantic N400 described earlier, this FN400 is thought to indicate memory processes related to the recognition of the discrepancy between old and new items. In their study, Masuda et al. (2014) compared European Canadian and Japanese participants, and found that both groups showed similar FN400 responses. However, the increased processing recruited for the old animal-new context pair only affected behaviors for the more holistic Japanese. The more Japanese processed the background as being new (seen through stronger FN400s), the more likely they were to mistake the old animal for being new. This gives direct evidence

that Japanese have difficulty ignoring processed contextual information in their memory judgments.

Cultural neuroscience research has also revealed other differences in attention (e.g., Goto, Ando, Huang, Yee, & Lewis, 2010; Hedden, Ketay, Aron, Markus, & Gabrieli, 2008; Murata, Park, Kovelman, Hu, & Kitayama, 2015). For example, previous work has shown that Asians have difficulty ignoring context in their judgments, whereas Americans have difficulty incorporating context in their judgments (Kitayama et al., 2003). In a functional magnetic resonance imaging (fMRI) extension of this work, Hedden et al. (2008) assessed the activity of the frontoparietal attention network (a neural index of effort that is required in tasks) and found a complementary pattern of activation for East Asians and Americans. This frontoparietal activation was greater for East Asians than for Americans when the task required them to ignore the context, whereas it was greater for Americans than for East Asians when the task required them to incorporate the context. In other words, East Asians and Americans showed neural patterns reflecting more effort when the task was not culturally preferred. These cultural differences seem to be robust, as they have been replicated in a recent cultural neuroscience study using functional near-infrared spectroscopy (fNIRS), adding evidence that nonpreferred cultural tasks do indeed lead to more cognitive effort (Murata et al., 2015).

In addition to this research, Goto et al. (2010) measured the extent to which people naturally attend to contextual information when asked to make judgments of focal objects. They compared Asian Americans' and European Americans' N400 ERPs in response to scenes consisting of foreground objects placed on background scenes, when the objects and scenes were congruent (e.g., a crab naturally fits on the beach) or incongruent (e.g., a crab does not fit as well on a parking lot). Related to the properties of the N400, a stronger N400 in response to the incongruent objects than to the congruent objects would suggest that the person was taking into account the foreground-background semantic fit. In line with cultural differences in thinking styles, Goto et al. found that only Asian Americans' processing showed a stronger N400 to the incongruent objects (vs. congruent objects), suggesting that only Asian Americans processed the relationship between the foreground objects and the background. Furthermore, social orientation was related to these N400 patterns,

providing further evidence for the role of social orientations in nonsocial contexts.

Culture and Dialecticism

Nisbett and his colleagues maintained that cultures also create other discourses that affect cognition and perception, such as Chinese naive dialecticism (e.g., Nisbett, 2003; Peng & Nisbett, 1999). Naive dialecticism emphasizes (1) the principle of contradiction (i.e., that things can have opposing contradictory states); (2) the principle of change (i.e., that things are always changing); and (3) the principle of holism (i.e., that things are interrelated and should be seen in context). In contrast, Western nondialectical thinking follows (1) the law of noncontradiction (i.e., A cannot equal not- A); (2) the law of the excluded middle (i.e., A is either B or not- B , there is no middle state); and (3) the law of identity (i.e., everything is only one thing, and different from others). In this section, we provide an overview of how differences related to dialectical and nondialectical thinking influence East Asians' and North Americans' cognition and perception.

The Principle of Contradiction

Researchers reason that in historic China, the Taoism and Confucianism schools developed dialectical logic to resolve contradictions, believing that two opposing states coexist as a form of active harmony (e.g., Peng & Nisbett, 1999). To investigate these beliefs related to contradiction, Peng and Nisbett presented Chinese and American participants with two scenarios from everyday life. One was a mother–daughter value conflict, and the other was a conflict between having fun and going to school. Then they analyzed the participants' responses, based on a coding scheme that distinguishes dialectical resolution from nondialectical resolution for each contradiction. The results showed that whereas Americans preferred to resolve the contradiction by choosing one side or the other (nondialectical resolutions), Chinese preferred to accept opposing contradictory states (dialectical resolutions).

Such tolerance of contradiction has also been found for self-perception. For example, Chinese, Japanese, and Koreans tend to report more self-contradictions than do North Americans (Choi & Choi, 2002; Hamamura et al., 2008; Spencer-Rodgers, Peng, Wang, & Hou, 2004), and this tendency is mediated by dialectical beliefs (Church et al., 2012). Recent fMRI research has also investigated how this tolerance of self-contradiction affects individuals' neural patterns (Wang et al., 2016). As a target measure, Wang and colleagues asked Chinese participants to judge whether conflicting and nonconflicting pairs of traits described themselves while measuring dorsal anterior cingulate cortex (dACC) activity. The dACC was a target because it plays a role in conflict monitoring and self-related processing. Results indicated that people with more dialectical beliefs showed more dACC activation to the conflicting traits. These results provided evidence that dialectical thinkers engaged more in the processing of contradictory information.

Investigators have also examined how dialectical and nondialectical thinkers deal with unexpected, contradictory information, finding that dialectical thinkers are more accepting of contradictory situations (e.g., a helpful person did not help, a selfish person helped; Choi & Nisbett, 2000; Yama et al., 2010).

The Principle of Change

According to the principle of change, the world is a web of cyclic relationships in flux. The yin–yang symbol, half black and half white, with the two halves swirled together, represents two opposing but interpenetrating forces that complement each other (Peng & Nisbett, 1999). These discourses are common in East Asian cultures, and prepare East Asians to expect change. To investigate the theory of change in Chinese and Americans, Ji et al. (2000) presented participants with scenarios and asked them about the probability of change after the events. For example, they asked how likely it was that two children who were fighting in kindergarten would become lovers someday. In line with cultural differences in dialecticism, Chinese were more likely than Americans to expect changes in the relationship over time. In other research, Ji, Zhang, and Guo (2008)

investigated how the theory of change affects decisions. When asked whether they would be willing to buy or sell stocks, Canadians tended to focus on recent price trends, selling if prices were going down and buying if prices were going up, whereas Chinese tended to expect changes in trends, buying when prices were going down and selling when prices were going up.

Spina, Ji, Ross, Li, and Zhang (2010) similarly found that dialectical thinkers would be more likely than nondialectical thinkers to assume that performance (e.g., athletic performance) would involve not only internal propensities but also some chance factors; that is, if there were multiple opportunities to measure phenomena, dialectical thinkers would predict that scores would “regress toward the mean” (Galton, 1886). For example, if the athlete’s first performance was extremely good, Chinese participants predicted that the second performance would not be as good. European Canadians, in contrast, did not predict such changes.

Other research suggests that the theory of change also affects how the two cultures perceive events over time (e.g., Brislin & Kim, 2003; Ji, Guo, Zhang, & Messervey, 2009; Maddux & Yuki, 2006; Spina et al., 2010). The reasoning was that if people perceive the world as cyclic, they refer to and place more importance on past states, as these states are an informative way to understand future events. On the other hand, if people perceive time as linearly flowing from past to present to future, never returning to the past, it is more reasonable to consider more immediate trends to best understand what will happen next. Several studies have converged to demonstrate supportive evidence for these assumptions. For example, when compared to European Canadians, Chinese are more likely to be sensitive to a person’s past behaviors, memorizing past events and perceiving the distance from the present to the past to be shorter (Ji et al., 2009). Also, Chinese are more likely to take into account more distant past trends in complex stock market decisions, and to place more monetary value on past events than on future events (Guo, Ji, Spina, & Zhang, 2012; Ji et al., 2008). Furthermore, Shechter, Durik, Miyamoto, and Harackiewicz (2011) showed that this wider temporal view affects learning motivations for the future, with East Asians expending more effort on learning for long-term benefits, and European Canadians expending more effort for short-term benefits. Kross and Grossmann (2012; Grossman & Kung, [Chapter 13](#), this volume) found that these time perspectives can be manipulated. When Americans were asked to imagine

events from a distant perspective (i.e., as if they were observing events from a distance) versus an immersed perspective (i.e., as if they were experiencing events themselves), participants were more likely to take on a dialectical perspective, believing that things would change in the future.

In terms of the internalization of the principle of change, several researchers have provided evidence that cultural learning processes play an important role in this process. For instance, Koo and Choi (2005) demonstrated that Korean students who studied Oriental medicine were more likely than those in other majors to endorse the principle of change when engaged in Ji, Nisbett, and Su's (2001) trend line task. Also, Ji (2008) examined the developmental trajectories of 7-, 9-, and 11-year-old Canadian and Chinese children's internalization of the principle of change and found that cultural variations increased with age, with cultural differences, becoming salient by age 11.

Holism

In addition to the principles of contradiction and change, dialectical thinkers perceive and are sensitive to relationships among phenomena, and are willing to understand the world holistically (Ji et al., 2004; Norenzayan, Smith, et al., 2002). As an example of this principle at work, Ji et al. (2000) demonstrated that Chinese were more likely than Americans to notice associations between events. Also, when Ji et al. (2004) presented participants with three concepts (e.g., monkey, banana, and panda), East Asians tended to group them according to thematic and holistic relationships (grouping monkey and banana together), whereas North Americans tended to group them according to taxonomic categories and common attributes (monkey and panda together).

Other researchers demonstrated that holism affects the scope of information attended to by dialectical thinkers. For example, Choi, Dalal, Kim-Prieto, and Park (2003) found that the more holistic Koreans took into consideration a greater amount of information in hypothetical murder cases than did Americans or Asian Americans. Similarly, L. Li, Masuda, and Russell (2015) found that when people are asked to make choices for hypothetical apartments, Hong Kong Chinese attend to more sources of

information than do European Canadians. Such patterns may also be seen in peoples' interpretation of emotional experiences. East Asians are thought to experience emotions holistically by attending to "multiple aspects of a given situation" (Shiota, Campos, Gonzaga, Keltner, & Peng, 2010), and are more likely than North Americans to perceive the co-occurrence of positive and negative emotions (Lu, Hamamura, Doosje, Suzuki, & Takemura, 2017; Miyamoto, Uchida, & Ellsworth, 2010; Spencer-Rodgers, Peng, & Wang, 2010). Furthermore, this co-occurrence of emotions has been related to the perception of happiness (Choi & Choi, 2002; Uchida, 2011; Uchida & Kitayama, 2009) and love (Shiota et al., 2010), and is related to health outcomes (Miyamoto & Ryff, 2011; Miyamoto, Yoo, & Wilken, [Chapter 12](#), this volume).

Finally, several researchers have further investigated the role of holism on decision making, reasoning that holistic exploration of information makes people more *indecisive* (the tendency to experience difficulty in decision making), because they take in many sources of information. They found that East Asians report more indecisiveness than do European Canadians (L. Li, Masuda, & Jiang, 2016; L. Li, Masuda, & Russell, 2014; Ng & Hynie, 2014), with higher dialectical scores explaining increased indecisiveness (Ng & Hynie, 2016).

Summary

Cultural psychologists have elucidated systematic cultural variations in cognition and perception. Westerners' inferences involve independent social orientation and analytic thinking styles, separating persons and things (events, objects, etc.) from context. In contrast, non-Westerners' inferences show the influence of interdependent social orientation and holistic thinking styles, taking into account the situational and contextual factors that surround persons and things. The two groups also differ in terms of discourses related to dialecticism. Non-Westerners, with their dialectical reasoning styles, tolerate contradiction, apply cyclic temporal perception, and use holistic information processing. In contrast, Westerners, with their nondialectical reasoning styles, apply noncontradictory judgments (similar to Aristotle's formal logic) and linear temporal perception, and use analytic

information processing (e.g., Choi et al., 2003; Hamamura et al., 2008; Ji et al., 2008; L. Li et al., 2014, 2016; Ng & Hynie, 2014; Ng, Hynie, & MacDonald, 2012; Varnum et al., 2010; Weber & Morris, 2010; Yates et al., 2010).

FUTURE DIRECTIONS

In this chapter, we have discussed a plethora of evidence showing that culture affects cognition and perception. The accumulated evidence suggests that cultural variations are gradually acquired through interactions with members of given cultures. This evidence includes behavioral and eye movement patterns, as well as neural patterns. In this final section, we discuss five issues that are important to future research: the East–West dichotomy, other sources of cognition and perception, cultural learning, cultural neuroscience, and individual- versus cultural-level phenomena.

Moving Beyond the East–West Dichotomy

As may be inferred from the results presented earlier, most of the research on cognition and perception has focused on the Eastern (e.g., Chinese, Japanese, Korean) versus Western (e.g., Canadian, American) cultures. Addressing this research bias, researchers have begun to examine other cultural groups. For example, researchers have examined differences between Italians and Americans (Federici, Stella, Dennis, & Hunefeldt, 2011), and between Americans, Western Europeans (British and Germans) and Japanese people (Kitayama, Park, Sevincer, Karasawa, & Uskul, 2009). Also, researchers have targeted within-country differences in social orientation and thinking styles. For example, differences have been found between northern and southern Italians (e.g., Knight & Nisbett, 2007; Martella & Maass, 2000). Further, there is a resurgence of research on acculturation (Mesquita, De Leersnyder, & Jasini, [Chapter 19](#), this volume). Other notable issues include religion (A. Cohen & Neuberg, [Chapter 32](#), this volume), social class (Kraus, Callaghan, & Ondish, [Chapter 27](#), this volume), and race (Mendoza-Denton & Worrell, [Chapter 28](#), this volume). These

investigations represent an important direction in research, as they demonstrate that cultural differences in thinking styles extend beyond simple East–West dichotomies.

Other Sources of Cultural Differences in Cognition and Perception

In this chapter we have emphasized the theoretical frameworks that explain cultural variations in cognition and perception under the rubric of social orientation (Markus & Kitayama, 1991, 2010; Varnum et al., 2010) and thinking styles (Nisbett, 2003; Nisbett et al., 2001), and have referred to specific findings under the name of economic and subsistence system (Uskul et al., 2008), religious beliefs (A. Cohen & Rozin, 2001), perceptions of honor (Nisbett & Cohen, 1996), and historically sustained ideas about political systems (Putnam et al., 1993). Other accumulated empirical evidence has enabled cultural psychologists to list a variety of other influences on human cognition and perception, such as tightness versus looseness of social structures (Gelfand, Nishii, & Raver, 2006), residential mobility (Oishi, 2010), voluntary settlement (Kitayama, Ishii, et al., 2006), and social class (Grossmann & Varnum, 2011; Snibbe & Markus, 2005; Stephens, Markus, & Townsend, 2007). In addition, current researchers have empirically examined the mechanisms underlying people's cognitions and perceptions by testing causal influences of culture through cultural priming studies (e.g., Hong, Morris, Chiu, & Benet-Martinez, 2000; Oyserman & Lee, 2008). Finally, several researchers have addressed the importance of a multifaceted understanding of the phenomena (e.g., Miyamoto, 2013). We believe that future research should continue to examine other factors that influence our cognition and perception.

Cultural Learning

In line with the idea that culture is slowly internalized, cultural-psychological research has begun to focus more on how cultural variations in social orientation and thinking styles are learned (Morris, Fincher, &

Savani, [Chapter 18](#)). Early research by Fernald and Morikawa (1993) revealed that Japanese and American mothers interact with their infants in manners that might support cultural differences in thinking styles. For example, when they interact with their infants, American mothers tended to point out the attributes of toys (i.e., color, shape, and numbers of parts), whereas Japanese mothers tended to emphasize the relationships between the toys, the mother, and the child. This finding is just one example of many showing that mothers convey culturally dominant practices and discourses to their children through direct interaction, even when their children are still very young (e.g., Azuma, 1993; Bornstein, Tal, et al., 1992; Bornstein, Tamis-LeMonda, et al., 1992; Wang, 2001, 2009; Wang, Leichtman, & Davies, 2000). Consistent with these initial findings, recent research indicates that parents directly influence children's cultural learning by providing them with messages about how to express their emotions (Tsai, Louie, Chen, & Uchida, 2007; Tsai & Clobert, [Chapter 11](#), this volume), interpret their emotions (H. Lee et al., 2017a), describe scenes (Senzaki et al., 2016), and color pictures (Ishii et al., 2014).

In addition to research on how culture is internalized, cultural psychologists have also started to examine *when* culture-specific thinking styles emerge in children's developmental courses (see Keller, [Chapter 15](#), this volume). To date, results suggest that children's thinking styles are socialized quite early for simple tasks, with cultural differences emerging by the age of 6 in face-selection tasks (Kuwabara, Son, & Smith, 2011), optical illusion tasks (Imada et al., 2013), picture coloring tasks (Ishii et al., 2014), and the framed-line task (Duffy, Toriyama, Itakura, & Kitayama, 2009). However, other findings suggest that when advanced reasoning is involved, cultural differences tend to emerge later, between ages 11 and 15 (Ji, 2008; Miller, 1984); while studies seeking to determine the ages at which variations emerge for tasks of intermediate difficulty showed cultural variations in cognitive task performance emerging around 9 to 10 (e.g., Imada et al., 2013; H. Lee et al., 2017a; Senzaki et al., 2016). To further this emerging area of research, we recommend future research on cultural learning, with investigations of why cultural learning related to cognition and perception occurs when it does.

Cultural Neuroscience

In addition to previous findings that highlight the importance of the influence of culture on our overt behaviors, cultural neuroscience has also begun to investigate how culture affects our brains (e.g., Chiao, 2009; Han et al., 2013; Kitayama & Tompson, 2010; Kitayama & Uskul, 2011; see Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume). Even though cultural neuroscience is still a relatively new field, research in this field has provided cultural psychologists with abundant evidence that culture directly affects our neural patterns related to cognition and perception. To facilitate discussion regarding this emerging direction of research, we briefly offer some thoughts for future work.

First, cultural neuroscience is not a replacement for other cultural-psychological methods. While some theories involving cultural neuroscience create grand original theories, such as the coevolution of genes and culture (e.g., Chiao, 2009), the reality is that most cultural neuroscience research is “small”; that is, it is process oriented and works to support previous theories rather than create new ones (e.g., Goto et al., 2010; Na & Kitayama, 2011; Russell et al., 2015; Varnum et al., 2012). Our belief is that cultural neuroscience is a wonderful tool that will allow a better understanding of processes involved in cultural differences. Each neuroscience method adds unique evidence for how culture affects our psychology. For example, with ERP methods, we can investigate various early attention processes that are different from what is assessed by eye-tracking or task behaviors (e.g., Masuda et al., 2012; Masuda et al., 2008b; Russell et al., 2015).

Beyond this, another strength is that cultural neuroscience helps reveal individual differences that mediate cultural differences. Although individual differences in cultural beliefs do not always support cultural differences in behaviors, often they have been shown to relate to neural patterns (e.g., Goto et al., 2010; Hedden et al., 2008; Ishii et al., 2010; Na & Kitayama, 2011; Russell et al., 2015).

Individual- versus Collective-Level Phenomena

To examine the issue of how culture affects individuals, researchers have devised self-report scales to measure cultural differences in social orientation and thinking styles (Choi, Koo, & Choi, 2007; Singelis, 1994; Spencer-Rodgers et al., 2017). These results indicate that East Asians have more interdependent, holistic, and dialectical beliefs than do North Americans (e.g., Hamamura et al., 2008; L. Li et al., 2014; Ma-Kellams, Blascovich, & McCall, 2012; Ma-Kellams, Spencer-Rodgers, & Peng, 2011; Masuda, Li, & Russell, 2018; Ng & Hynie, 2014; Spencer-Rodgers, Boucher, Peng, & Wang, 2009). We might then expect that individuals' cultural beliefs on these scales would relate to individuals' behaviors on cognitive and perceptual tasks. However, recent evidence suggests that correlations between individuals' self-report scores and behavioral patterns are weak at best (e.g., Na et al., 2010; Spencer-Rodgers et al., 2017; Weber & Morris, 2010). For example, there are cases in which East Asians showed interdependent (or holistic) behavioral tendencies; however, the subjective perception of their level of interdependence is not strong, which results in a weakened association between their cultural behaviors and beliefs.

Several cultural psychology research groups have addressed this discrepancy by advocating the refinement of theoretical assumptions related to culture (Kitayama et al., 2009; Na et al., 2010). For example, Na and colleagues reasoned that according to Shweder's (1991) assertions regarding the theoretical bases of cultural psychology, the target of analysis of cultural psychologists has actually been cultural-level phenomena—socially shared patterns of behavior. These patterns are represented as a form of average value for each cultural group rather than individual-level phenomena; that is, even though a culture-specific pattern of cognition and perception is observed in aggregated data, such a phenomenon is not always reducible to individuals' minds. The most salient target of cultural-level analyses are cultural products: tangible, public, shared representations of culture, such as magazine advertisement, laws, newspaper articles, TV comments (Heine, 2015; for review, see Morling & Lamoureux, 2008).

Recently, theoretical frameworks for these cultural-level variables have been further investigated and developed, including the intersubjective model (Chiu, Gelfand, Yamagishi, Shteynberg, & Wan, 2010) and the cultural dynamics model (Kashima, 2014). These researchers maintain that although there are substantial individual differences in how much people

internalize culturally shared behavioral patterns and how consistent their cultural beliefs are with their behaviors, people tend to similarly infer surrounding others' behaviors. If so, beyond the *methodological individualism*, common to current cultural psychology, focusing on individuals' behaviors, researchers need to instead focus on *cultural-level variables* and collect data related to individuals' inferences of common behaviors in a given culture. Mature members of a given society can infer potential outcomes of their behaviors, related to reactions from other members of their culture, and adjust their behaviors according to these inferences. Intersubjective theories assume that (1) this pattern is the foundation of people's social behaviors, and (2) people's cognitive and perceptual patterns are more likely to follow their cultural beliefs and values when social context is made explicit (compared to an absence of social context).

On the other hand, we believe that we also need to rethink how we assess the coherence of cultural constructs. How could we better capture consistency? Conceptually, it may be better to restructure how each construct is nested with other constructs, by reorganizing the relationships between target constructs and measures. For example, several tasks were devised to measure similar subconstructs within holistic versus analytic thinking styles. Would consistency be stronger among more similar tasks? Would individuals' cultural beliefs better explain cultural differences for these tasks? With these thoughts in mind, we believe that future research needs to work toward further refining theory related to individual- versus cultural-level phenomena.

CONCLUSION

In this chapter we have provided an overview of findings targeting the influence of culture on cognition and perception. We have offered various accounts to explain cultural differences in cognition and perception, including ecology, subsistence systems, social orientation, and cultural practices and discourses (e.g., Nisbett & Cohen, 1996; Varnum et al., 2010). Regardless of the origins of cultural differences in cognitive and perceptual processes, research has shown that culture has a deep influence on people.

These differences are important, as their fundamental nature makes them related to all other domains in cultural and mainstream psychology, addressing the well-debated issues of the universality and cultural specificity of psychological processes (Boland, Chua, & Nisbett, 2008; Bruner, 1990; Chua et al., 2005; Evans, Rotello, Li, & Rayner, 2009; Fodor & Pylyshyn, 1981; Geertz, 1973; Markus & Kitayama, 1991; Miller, 1999; Pylyshyn, 1999; Rayner, Li, Williams, Cave, & Well, 2007). While current findings are extensive, we believe that this area of research still holds many unanswered questions related to the coherency of cultural constructs, their internalization, and their relationship to biological processes.

CHAPTER 9

Culture and Language

Jeffrey Loewenstein

Culture requires regularities. Culture is something we do together, over and over again. Cultural conventions accumulate into practices, meanings, and values. We can view language as a ubiquitous tool for generating massive, intricate, distributed systems of conventions. We then use these linguistic conventions to coordinate our behavior, to work together, to engage with one another, and to create much larger and more encompassing cultural worlds than we could otherwise. Looking at language as a system of cultural conventions provides an opportunity to integrate research from multiple disciplines and levels of analysis. Looking at the breadth of linguistic conventions indicates how pervasively language gives shape to cultures. And looking at how ensconced in culture language is serves as a reminder that language does not stand apart but rather is created and used, messily, by vast numbers of people, constantly, within cultural communities.

Languages, like all other aspects of culture, involve cooperation, require learning, and are made of systems of collective conventions (Clark, 1996). As a result, understanding how language works requires attending to how culture works. Given how pervasive language is in human culture, the reverse is true as well. At the center of both culture and language are conventions.

The humble beginnings of isolated conventions can seem arbitrary or simply silly. Many groups celebrate with rituals such as ringing bells or sharing pizza; some groups pass bananas or gift spray-painted beer bottles. These are collective, intentional acts that generate mutually understood meanings through collaborative agreements. In stating that ringing the bell

marks an outcome as a victory for our group, we make it so (Searle, 2010). Simple conventions are most apparent when joining a new group or when engaged in pretend play with a preschool child, agreeing that some stick, plastic fork, or rubber band is a microphone, hairbrush, or crown (Tomasello, 2014). As more conventions are added, the isolated ritual becomes part of a system. The convention might initially have been arbitrary, local, and simply a convenience, but then we build a collection of other conventions around it, bolstered by artifacts. We travel on the right or left side of the path and eventually accumulate signs, lights, laws, and police actions. Initial choices, once collectively established and elaborated into larger systems of conventions, become powerful. The contexts in which conventions apply can grow to be so encompassing and the influence of conventions for enabling and constraining behavior so great that we forget that these are conventions at all. They just feel like worlds. Languages are systems of conventions like that.

Systems of linguistic conventions range in coherence and complexity. We have a fair amount of leeway in forming naming conventions, for example, deciding to call this person Jaclyn or that place Chicago. We have somewhat less leeway in generating conventions about words for types—these kinds of things are chocolates, those kinds of things are smiles. We have much less leeway, and usually take for granted, a host of other, more pervasive and interdependent conventions such as those regarding how to pronounce words, the order in which to say words when using more than one of them, the direction in which to write words, and the need to mark aspects of meaning such as when something happened or what kind of entity is being described. Considering conventions of various kinds will be the focus of most of what follows.

Before considering conventions further though, it is helpful to clarify that using a language, like everything else people do, rests on more than conventions. Humans appear to be prepared for language, with bodies specialized for it and inclinations for it that seem internally driven (Dediu et al., 2013; Goldin-Meadow, 2005). Yet as with other discussions of nature and nurture, of individuals and collectives, and of structure and agency, it is more fruitful to explore the interactions than it is to crown one cause king.

For example, color words have long been of interest to scholars of culture and language (Berlin & Kay, 1969; Kay & Regier, 2006). Part of an

analysis of color must be the mechanisms for how our eyes and brains process light. Human physiology is likely responsible for differences in discrimination across the electromagnetic spectrum. Another part of an analysis of color must be the mechanisms for how people agree on how to use words to refer to something. Combining the effects of color perception with the effects of forming conventions goes a long way toward explaining color categorization patterns in cultures around the world (Baronchelli, Gong, Puglisi, & Loreto, 2010). Cultural evolution and biological evolution, even if they are theoretically separable, seem better studied together (Boyd & Richerson, 2005).

The same value from studying concerns together rather than separately holds for language and thought (Enfield, 2015; Wolff & Holmes, 2011). Language, like most of culture, is enmeshed in our thinking (Vygotsky, 1986) by habit, by need, and because it is so useful. Languages differ in how easy and difficult they make it to express some notions, which must have some effects on thinking, including what we think about habitually (Hunt & Agnoli, 1991). Languages force us to express notions using particular words, put together in particular ways, and with particular sounds. This must have some effects on thinking, including what we need to think about during the vast majority of our lives when we are using language (Slobin, 1996). Languages provide tools for thinking, which also must have some effects of thinking, including helping us to develop and apply expert knowledge (Gentner, 2016). Consequently, in studying language and human culture, cognition is necessarily involved.

To keep the focus on language and culture, we will simply rely on several assumptions. We will assume that there are regularities, consistencies, symmetries—structures—in the world. We will assume that people, like other living organisms, have perceptual and cognitive capacities to sense and respond to at least some of those structures, as well as motor capacities (including those needed to use languages) to act and create new structures. We will assume that people can form an unlimited number of interpretations of those structures. We will assume that people, like other living organisms, have limited and directed cognitive capacities, and so select and use just some of those interpretations. We will assume that groups of people—cultural communities—can form conventions. We will assume that languages offer one symbolic system with which cultural communities

form conventions. We will assume that conventions are structures that individuals might perceive, interpret, remember, and use to guide their own thinking and action. With that, we can turn to examining linguistic conventions.

LINGUISTIC CONVENTIONS

Arthur C. Clarke (1973) proposed that “any sufficiently advanced technology is indistinguishable from magic.” Language is in a sense an advanced cultural technology and so examining linguistic conventions is a bit like venturing behind the curtain to study how the magic is made. Linguistic conventions, such as how formal to be when speaking in different social contexts (Halliday, 1978), might seem obvious as cultural products, as well as interesting and important ones. Yet these risk failing to convey how fundamental conventions are to language. Conventions about words are perhaps more indicative.

We rely on words, like *dog*, *under*, *organization*, *stakeholder*, *creativity*, and *cooperation*, to mean something. It is natural to talk about word meanings. We are aware that words mean something to speakers of a language and not to those who do not speak the language. We are aware that there are words, usually technical terms, we do not know, even in a language we speak. Physicians talk about *plasmapheresis* as being important, a *writ of mandamus* is important in the legal community, and *false gills* are important in the mycological community. The words seem, by some sort of magic, to mean something on their own, apart from us and our individual understandings of them.

To make sense of the intuition that words have meanings, we need to bring in the idea of a cultural community. A word is meaningful because people within some cultural community use the word, by convention, in particular ways (Clark, 1998; Wittgenstein, 1953). For example, any look in a newspaper shows that we talk quite a bit about organizations: A school is an organization, a church is an organization, and we have business organizations and government organizations. “Organization” is a superordinate term for a social collective with some formal structure that can act and make commitments as a unitary entity. At least, we can say that

this is approximately how the word *organization* has been used in roughly the past 100 years in English speaking societies, but not before (Starbuck, 2007). This corrective due to taking a historical perspective is one indication that word meanings are bound to cultural communities located in particular historical eras.

Another common word, *stakeholder*, provides a second corrective. It is a parody of corporate executives at this point that they seem constantly engaged in strategic planning sessions on how to engage their stakeholders with visions of innovative futures. The term *stakeholder* appears to refer to something central and important. For example, in a speech at the United Nations in 2005, the U.S. Deputy Secretary of State at the time, Robert Zoellick, gave a speech whose central message was “We need to urge China to become a responsible stakeholder” in global society. Yet apparently the term *stakeholder* was so taken for granted by U.S. State Department diplomats that they failed to consider that the word had no ready translation into Chinese (King & Dean, 2005). It is hard to argue that Chinese has an underdeveloped terminology for social relationships. However, this was no guarantee of a ready match to contemporary American social jargon.

Words like *organization* and *stakeholder* are common enough that we can forget that they are cultural inventions and complex enough that we can imagine having converged on somewhat different meanings. We might have converged on another way of grouping social collectives than organizations. We might have considered the network of related entities in another way apart from stakeholder. These words, *organization* and *stakeholder*, are in routine use. They do not even have the richly layered meanings of words such as the American use of *liberty*, the Yiddish *chutzpah*, or the Viennese *schmäh* (Agar, 1994). Still, *organization* and *stakeholder* are words used according to particular conventions within particular cultural communities at particular points in time. Words do not mean something on their own, now and forever, and for everyone.

With words like *dog* and *under*, it can be difficult to appreciate the role of a cultural community in shaping their meanings. It is easy to wonder whether we arrive at some more basic notion of “dogness” that is somehow a product of nature and we are merely labeling it. In examining reviews on this question (e.g., Ojalehto & Medin, 2015; Wolff & Holmes, 2011), it becomes clear that most of the discussion of how structures in the world

influence word meanings centers on meanings for concrete types of things in the world (Gentner & Boroditsky, 2001). We can discuss the physical properties of *bottles* (Malt, 2010), the spatial arrays considered *under* or *above* (Coventry, Prat-Sala, & Richards, 2001; Carlson-Radvansky & Irwin, 1994), the physical properties of movements considered to be *jumping* (Malt et al., 2008), or the chemical properties of the smell of *chocolate* (Doty, Shaman, Kimmelman, & Dann, 1984; Majid & Burenhult, 2014). In contrast, for meanings like *organization* or *stakeholder*, there is much less discussion of structures in the world shaping meanings. Yet we use these less concrete kinds of words frequently and find them every bit as meaningful.

Even for words for concrete kinds, like *dog*, as with color words, there is still an important role for conventions. The prior objects that have been called bottles, for example, guide what future items are called bottles (Xu, Regier, & Malt, 2016). Furthermore, there is still a cultural aspect to the meanings of these words that goes beyond any observable physical properties. For example, there are culturally shaped frequencies of dogs, culturally shaped typical kinds of dogs, and culturally shaped ways of treating dogs, among other aspects of meaning. These cultural conventions in turn shape the physical properties of dogs, as dogs themselves have been shaped through selective breeding. The general point is that there is a feedback loop between understandings and actions on the one hand and structures in the world on the other hand. It is probably meaningless to try to define the point at which we are no longer talking about the physical nature of specific entities and are talking about a culturally specified and shaped set, with culturally emphasized properties and tendencies. It is also probably meaningless to try to say at what point we are no longer talking about the meaning of the word *dog* and instead are talking about the cultural beliefs related to the word *dog*. Many meanings that we form are understood with respect to their relationships with other items (e.g., Bowerman & Choi, 2003; Collins & Loftus, 1975; Goldstone, 1996). The larger point is that word meanings reflect more than minimal properties or physical descriptions. They also reflect cultural elements, including histories and typical social concerns (Loken, Joiner, & Peck, 2002) such as attitudes, values, motives, and contexts of use. The meaning of *dog* and the meaning of *cockroach* are not simply concerned with anatomical observations.

A different challenge arises with words like *creativity* and *cooperation*. These words, despite not being concrete, are so commonplace and seem so natural that, like *dog*, they seem to have meanings that mark out fundamental structure in our world. We talk of people cooperating, nations cooperating, chimpanzees cooperating, and plants cooperating (Wu, Diggle, & Friedman, 2013). We can think of the examples labeled by these words as forming a grouping that would seem to exist even apart from our labeling of it. Yet cross-cultural analyses show substantial differences in lay beliefs about the meanings of *cooperation* and *creativity*. For example, in a cross-cultural study of cooperation (Keller & Loewenstein, 2011), most Chinese respondents reported that competing within one's team was cooperative, whereas most U.S. respondents reported that competing within one's team was not cooperative.

Creativity shows similarly striking differences. In a study of creativity, most Chinese respondents reported that a product being targeted for a mass market was indicative of creativity, and most Chinese respondents, when given an item described as being for a mass market, rated it as being creative. In contrast, for most U.S. respondents, being an item for a mass market was indicative of noncreativity and items described as being for a mass market were rated as being noncreative (Loewenstein & Mueller, 2016). Perhaps the biggest challenge in appreciating the role of culture for words like *cooperation* and *creativity* is simply stopping to consider the possibility. The research communities studying cooperation and creativity tend to start with researcher-generated definitions and do not consider the cultural beliefs about cooperation and creativity that are the starting point for most laypeople. The same tendencies pervade social science research well beyond those researchers studying cooperation and creativity.

Cooperation is a culturally shaped social process and it is also a word. Words have meanings because cultural communities establish those meanings. Individuals form understandings of those culturally generated word meanings and use their understandings to guide their uses of the words and their interpretations of what others say and do. Examiners measure whether children know the meanings of words in schools, and scholars examine children's understandings of words in developmental research. We treat word meanings as facts but often leave implicit that these

are cultural facts. A word's meaning is a collective product. As Putnam (1973, p 704, emphasis in original) put it, “ ‘meanings’ just ain't in the *head*.”

Putnam (1973) goes still further, because as is clear from the examples of plasmapheresis, writ of mandamus, and false gills, meanings are not in many of our heads. We have divisions of labor—some of us are teachers, others are mechanics, still others are actors (Durkheim, 1893/2014). We have divisions of cognitive labor—some of us know about bicycles and others of us know about bisons (Keil, Stein, Webb, Billings, & Rozenblit, 2008). We also have divisions of linguistic labor—some of us get to decide what gets called *red snapper* and the rest of us just take their word for it (Putnam, 1973). One sign of the power of the division of linguistic labor is that, according to Oceana (oceana.org), most people purchasing red snapper in the United States between 2010 and 2012 were not actually getting red snapper. The level of understanding a typical individual needs to use a word is less than what we probably want to call the word's meaning. After all, the level of understanding a typical individual needs to use a car is less than what we probably want to call a complete understanding of cars. The cultural community's meaning is not some simple average or aggregate but rather is disproportionately shaped by linguistic experts (Loewenstein, 2014; see also Romney, Weller & Batchelder, 1986). Those linguistic experts are shaping conventions that others can follow.

To generate meanings for words, whether *dog*, *organization*, *cooperation*, or *red snapper*, we produce and maintain a range of cultural conventions. We rely on conventions about pronunciation and about spelling to maintain the consistency needed across instantiations to know that we are using the same word. We rely on conventions about what examples we can and cannot label with the word, as well as conventions about what words go together with other words to know if we are using the word in the same way as others (Loewenstein, Ocasio, & Jones, 2012). These are conventions built up and maintained over time as large collections of individuals engage in a host of distributed and often asynchronous interactions that, typically, as a side effect of coordinating their behavior (Garrod & Pickering, 2009), encourage them to align their understandings (Goldstone, 2015). Following the division of linguistic labor, some members of our cultural communities have disproportionate influence to use particular words and so disproportionately shape the conventions about what those words mean for the community.

Some media outlets gain disproportionate influence through the scale of attention they capture (Fusaroli et al., 2015). Some communications—stories, videos, songs—have disproportionate impact (Loewenstein & Heath, 2009; Salganik, Dodds, & Watts, 2006). Word meanings are complex products of systems of conventions within cultural communities. A word is only meaningful in the context of some cultural community, and many people can use a word despite having only a modest understanding of its full cultural meaning by following conventions that others set.

Linguistic Conventions Are Cultural Obligations

Cultural conventions yield not only word meanings but also social force in the form of evaluations and obligations. Cultural conventions about words, and many other aspects of language use, are norms (Morris, Hong, Chiu, & Liu, 2015b). They are not only focal points or indications of what is typical to do but also are prescriptions about what one ought to do (Searle, 1995). Linguistic conventions, like norms generally, “exist in the objective social environment in the form of behavioral regularities, patterns of sanctioning, and institutionalized practices and rules. They exist subjectively in perceived descriptive norms, perceived injunctive norms, and personal norms” (Morris et al., 2015b, p. 1). For example, due to U.S. cultural conventions about what counts as proper pronunciation in news broadcasting, a single word pronounced as *-in'* instead of *-ing* (e.g., *puttin'* instead of *putting*) led observers to an average of a 2.5-point drop on a 7-point scale in mean ratings of professionalism (Labov et al., 2011). This effect was weaker for younger, lower-socioeconomic-status, and minority participants, consistent with the possibility that the harshest judgments and so the most vigorous policing of dominant cultural norms is done by those most committed to the dominant cultural norms.

Our willingness to judge others based on their adherence to linguistic conventions indicates the power of those conventions. That power extends inward as well. For example, U.S. and Polish individuals' assessments of their own thoughts and behavior showed no difference in collectivism, but Polish individuals perceived higher collectivism as their cultural convention (Zou et al., 2009). It was perceived cultural collectivism, not their own

inclinations, that then shaped participants' responses. The normative power of conventions can override our personal leanings to shape our behavior, as countless studies of social influence tell us.

Also showing the power of cultural conventions, naming practices can override deductive logic. For example, Indonesian linguistic conventions are to refrain from calling humans *animals*. Upon being asked if humans are animals, no more than 15% of Indonesian 6-year-olds, 9-year-olds, or adults, agreed, while most agreed that humans are mammals, and that mammals are animals. After engaging in a logic task illustrating the transitivity of class inclusion, over 80% of the children then agreed that humans could be called animals, but over 60% of the adults continued to refuse that naming pattern (Anggoro, 2014). When asked for justifications, most adults simply reiterated that humans are not animals, while some explicitly refused the logical deduction or noted distinctive properties of humans (including "Humans have reason"). These findings speak to the obligations to follow linguistic conventions.

Obligations not only shape current thinking and behavior but also work to maintain systems of linguistic conventions. For example, individuals often learn cultural practices simply by being given instructions rather than enduring an elaborate trial and error shaping of their behavior (Lupyan & Bergen, 2015). Instructions yield practices and behaviors that are then more likely to be passed on and stably maintained by cultural newcomers than are observations without instructions (Kashima et al., 2015; Zucker, 1977). The instructions provide indications of the applicable categories, roles, and rules, which can then channel perception and action. Newcomers typically look to oldtimers for what to do, and use oldtimers' language and behavior to understand situations and select appropriate actions. Oldtimers also sanction newcomers if they do not follow conventions and so enforce norms (Tomasello, 2014). Patterns in the language use we experience provide expectations about descriptive norms (Kwan, Yap, & Chiu, 2015). Today's descriptive norms can become tomorrow's injunctive norms (i.e., obligations), as illustrated in confusions over what dictionaries are (Pinker, 2012). Injunctive norms can then become institutionalized to shape behavior still more broadly and stably (Morris et al., 2015b). Such norms might hold at both the level of particular groups, organizations, or professions, and the level of societies, such that simply using a particular

natural language (e.g., English or Chinese) can encourage individuals to adopt particular mindsets and their attendant obligations (Chiu, Leung, & Kwan, 2007). For example, Hong Kong students showed a greater tendency to self-enhance when asked about themselves in English than in Chinese (Lee, Oyserman, & Bond, 2010). Thus, while linguistic conventions are surely informational focal points for coordinating behavior (Clark, 1996), they are also obligations that indicate attitudes, motivations, and values (Mills, 1940).

There Are Many Kinds of Linguistic Conventions

Many kinds of cultural conventions can influence behavior, but language plays a distinct role. We are socialized into linguistic conventions from an early age and treat language as a distinct set of conventions. Infants appear to tune to human speech sounds, distinct from other kinds of sounds, by about age 3 months (Vouloumanos & Waxman, 2014). By about age 9 months, infants expect that the words a speaker uses to label objects will be used by other speakers, whereas they do not expect a speaker's preferences for one object over another to generalize to other people (Henderson & Woodward, 2012). Accordingly, by about age 1 year, infants seem to assume that language use indicates an attempt to communicate information. For example, in one set of studies, infants tended to look longer (i.e., show surprise) when a speaker using nonsense speech, as opposed to coughing, led a listener to pick up a nonfocal object rather than a focal object, indicating a failure to communicate (Martin, Onishi, & Vouloumanos, 2012). Then, by their second year, young children tend to accept language more readily than gestures or nonhuman noises as having a symbolic role for marking meanings (Namy & Waxman, 1998; Woodward & Hoyne, 1999). Furthermore, in their second year, young children who speak one language are surprised by adults who understand more than one language, whereas bilingual children are not (Pitts, Onishi, & Vouloumanos, 2015). The larger pattern across these studies is that young children rapidly learn that we use natural languages as privileged symbolic systems for communicating information within social communities.

The question then becomes what kinds of conventions we generate and use as a result of relying on language as a privileged symbolic system for communicating information within a social community. The following sampling of conventions is intended to illustrate their variety and influence.

Script Direction

Once we enter into a particular community, we learn and then become subject to following that particular community's linguistic conventions. And as language is pervasive, the effects of linguistic conventions are too (Slobin, 1996). For example, some languages are written left to right (e.g., English, Greek), but other choices are available, such as right to left (e.g., Hebrew, Arabic) or top to bottom (Mongolian, and sometimes Chinese and Japanese). This seems about as arbitrary as the side of the road on which we drive. Yet the direction in which we read and write does seem to have consequences.

For example, German and Israeli preschool children—who are not yet competent writers and readers—showed no preference in ordering pictures of an agent, action, and the object that was acted upon (Dobel, Diesendruck, & Bölte, 2007). In contrast, German and Israeli adults showed a tendency to follow standard script directions in typical declarative sentences (the agent acted on the object): The Germans put the agent on the left and the Israelis put the agent on the right. Similarly, Italian adults tend to draw actions happening left to right, whereas Iraqi (Arabic-speaking) adults tend to draw actions occurring right to left, again consistent with script direction (Maass & Russo, 2003). Script direction is not the only influence on ordering actions. The conventional grammatical structure of a sentence, such as agent–action–object (as in English) or action–object–agent (as in Malagasy, a language spoken in Madagascar) can also be the convention governing how individuals match language to scenes (Maass, Suitner, & Nadhmi, 2014). We can be influenced by multiple linguistic conventions, after all. Yet script direction does seem to be a reliable influence on how adults map time onto space (Fuhrman & Boroditsky, 2010).

The effect of script direction on mapping time to space is just a beginning, as it leads to further inferences and judgments. For example,

videos of soccer goals were shown to adults, with the action occurring either left-to-right or right-to-left. When the videos followed conventional script direction, Italian-speaking and Arabic-speaking adults found them to show greater strength, speed, and beauty than when the videos showed the actions as occurring in the opposite direction as the conventional script direction in their language (Maass, Pagani, & Berta, 2007). Similarly, Italian-speaking adults tend to place pictures of more agentic actors on the left of less agentic actors, whereas Arabic-speaking adults tend to place them on the right of less agentic actors (Maass, Suitner, Favaretto, & Cignacchi, 2009). Thus, linguistic conventions about script direction provide defaults that then set up fluency and fit effects that guide perceptions.

Pronunciation

We speak languages, and in speaking we have choices about pronunciation. Sociolinguistic studies of variation (Eckert, 2012) have been particularly effective in mapping out how pronunciation is strongly shaped by and for the purposes of cultural communities. For example, increases in Chinese development and globalization led to the rise of young urban professionals in Beijing. This is a group of relatively wealthy, often single, working adults employed not in state-owned enterprises but in global firms. This group developed distinct pronunciation patterns, minimizing some of the strong local tendencies toward smoother speech (rhotacization) that at the time served as a marker of a distinctive, stereotypical “Beijing Smooth Operator” (Zhang, 2008), and adding pronunciation patterns from cosmopolitan Chinese speakers (e.g., in Hong Kong and Taiwan; Zhang, 2005). The result is a system of linguistic conventions about pronunciation that help mark a distinct social community.

In a similar fashion, pronunciation patterns were part of social group identities and distinctions among Latina youth gangs and other young women in Northern California (Mendoza-Denton, 2008). Particular pronunciation features, such as creaky voice, can signal membership in a social community, particularly when several distinctive features are combined into distinctive ways of speaking. Individual features can also be isolated and transferred to other social groups in a form of borrowing, as

groups influence other groups (Mendoza-Denton, 2011). There is a wealth of sociolinguistics research using pronunciation as a marker of social group identification and interaction; these examples are just a small sampling of that exciting literature.

A different aspect of pronunciation lies with a variety of work on accents. For example, one claim is that accents serve as a readily observable tag that someone is (or is not) a member of the same community (Kinzler, Dupoux, & Spelke, 2007). Accents are not particularly easy to fake. They generally require a fair amount of socialization and close contact to master. Consequently, there is a proposal that cooperating with someone with the same accent is a reasonable bet (E. Cohen, 2012). Kindergarten children appear to prefer those who speak with their own accent rather than a foreign accent, including when they have to cross racial categories to do so (Kinzler, Shutts, DeJesus & Spelke, 2009). Some even believe language is more enduring than race (Kinzler & Dautel, 2012).

As further support of the idea that accents indicate cultural group membership, accents do appear to indicate specific cultural beliefs. For example, hearing accents shifts bicultural individuals to apply cultural frames from the culture indicated by the accent (Dehghani, Khooshabeh, Nazarin, & Gratch, 2014). Although both appearances and accents can indicate ethnic categories, when the two diverge, observers tend to rely more heavily on accents (Rakić, Steffens, & Mummendey, 2011). And when individuals are perceived to have behaved in culturally inappropriate ways, people form less negative attributions when the individuals have a foreign accent than a local accent (Molinsky & Perunovic, 2008). It is not that an accent allows people to forgive poor intentions, but rather that accents are a signal to forgive cultural unfamiliarity, as a study of e-mails with both impolite statements and grammatical errors revealed (Vignovic & Thompson, 2010). Accents, like other patterns in pronunciation, are social indicators, because they are community-generated conventions that are a necessary part of spoken communication.

Metaphor Choice

Cultural conventions are also concerned with content, such as conventions about what metaphoric bases to use to understand the world. There are long-standing observations about the role of metaphor in understanding space, time, number, and other fundamental concerns (e.g., Lakoff & Johnson, 1980). As there are many possible matches, conventions have a role in selecting collective defaults. For example, sweet tastes may seem to map onto positive attributions to a person (“He was so sweet”), but Israeli culture seems to map sweetness onto inauthenticity and so to negative attributions (Gilead, Gal, Polak, & Chollow, 2015). Cultures can choose metaphoric bases and how to map them.

As a further example of selecting metaphors, while *kiki* might seem as if it applies to angled shapes and bitter tastes and *bouba* might seem as if it applies to rounded shapes and milder tastes, that too seems subject to cultural convention, as indicated by differences between Himba and American participants’ tendencies in matching tasks (Bremner et al., 2013). Or musical pitch can readily be mapped to verticality (high or low, as done in English) or thickness (thin or thick, as done in Farsi), and which metaphor is used in a language is subject to convention (Dolscheid, Hunnius, Casasanto, & Majid, 2014). These examples, and many more like them by these scholars and many others, indicate that the mappings we make from one domain to another rest on some meaningful similarities, but that the particular basis in use is a matter of what a particular community selects as its convention.

Abstraction

Another aspect of conventions are conventions about what kinds of words to use when communicating. For example, two streams of research seem to be converging on the importance of cultural conventions that emphasize tendencies to rely on abstractions or specific concrete events: research on the linguistic category model (Semin & Fiedler, 1988) and research on generics (Gelman, 2003).

The core claim from the first stream of work following from the linguistic category model is that descriptions vary in attributing effects to situations or people (Maass, Montalcini, & Biciotti, 1998). We might

describe an event by using a verb to describe the action, such as “Shiyu instructed the class on the material.” We might describe it using an adjective, such as “Shiyu is instructive.” We might also use a noun, such as “Shiyu is an instructor.” The progression from describing a specific action to describing the actor indicates a progressively more abstract and general claim (Carnaghi et al., 2008). Descriptions using nouns as opposed to adjectives tend to be taken as more indicative of the essence of the actor, are stronger predictors of other traits about the actor, and tend to be used in communications when speakers believe the descriptions are indicative of the actor’s essence (Carnaghi et al., 2008; Maass, Cadinu, Boni, & Borini, 2005). It is of interest then that linguistic conventions vary in their tendencies towards abstractness. For example, Italian speakers tend to use more adjectives and fewer verbs to describe people than Japanese speakers, and Italian speakers also tend to jump from behavior to traits more readily (Maass, Karasawa, Politi, & Suga, 2006).

The work on the linguistic category model has tended to focus on the contrast between verbs and adjectives, with newer work focusing on nouns. Work on generics has focused on ways of using nouns. For example, we might say, “The horse was eating a carrot,” or we might say, “Horses eat carrots.” In the second case, we are not describing any particular horse but making a more abstract claim about horses in general (Gelman & Ware, 2012). People tend to interpret generic claims as expressing central, underlying concerns about the category (Cimpian & Markman, 2009), the kind of information that many people would know about a category (Cimpian & Scott, 2012), and an indication that the category is not simply a temporary social construction but perhaps a natural kind (Gelman, 2003). Accordingly, it is important that communicating can foster the formation of essentialist views of social categories (Kashima et al., 2010), and that adults who believe a category has an underlying essence tend to use generic language when talking to children about that category (Rhodes, Leslie, & Tworek, 2012). Thus, there is likely a self-reinforcing pattern of cultural transmission, through generic language use, regarding essentialist beliefs.

Combining the work on generics with the work on the linguistic category model, the implication is that cultural conventions about using abstract language can inculcate essentialist beliefs about categories, thereby increasing community commitments to those categories and the inferences

that follow regarding members of those categories. For example, people tend to perceive female marked words (*chairwoman, waitress*) as connoting less status than male (*chairman, waiter*) or neutral (*chair, waitstaff*) words (Merkel, Maass, & Frommelt, 2012). Using nouns in communication to refer to people by female marked words for roles then could well lead to believing in the lower status of the individuals within those roles, due to inferring that there must be something lesser that is intrinsic to the holders of those roles (Salomon & Cimpian, 2014). Conventions about the kinds of words we choose to use are clearly consequential.

Category Relations

As a final example of the breadth of the conventions that cultures instantiate in language, work on paradox is showing remarkably broad tendencies for how to handle relations between opposing categories. Specifically, there appears to be a general contrast in integrating paradoxes and tolerating oppositions between East Asian cultures and Western cultures (Peng & Nisbett, 1999; Spencer-Rodgers, Williams, & Peng, 2010). This seems to have far-ranging consequences. For example, in a longitudinal study, Perunovic, Heller, and Rafaeli (2007) found that when bicultural and bilingual individuals had recently spoken an East Asian language, their experience of positive and negative affect were positively correlated, whereas when they had recently spoken a Western language, their experience of positive and negative affect tended to be negatively correlated. The relationship between the two categories shifted with cultural conventions about how to handle paradoxes.

A similar difference in integrating or separating opposing categories is also appearing in work on cooperation and competition. While both U.S. and Chinese dictionaries list *cooperation* and *competition* as antonyms, Chinese individuals tend to report adopting cooperative and competitive orientations simultaneously (Chen, Xie, & Chang, 2011). Furthermore, Chinese individuals tend to report that competing within a team is cooperative, and if someone on their team competes with them, they share knowledge (i.e., take cooperative actions) with them. In contrast, U.S. individuals tend to report that competing with a team is noncooperative,

and if someone on their team competes with them they tend not to share knowledge with them (Keller & Loewenstein, 2011; Keller, Loewenstein, & Yan, 2017). What *cooperation* means and how it relates to *competition* appear to be shaped by general cultural stances toward handling paradoxes and spreads as part of the semantics of the words and conventions for using those words.

Taken together, the work on category relations, abstraction, metaphor choice, pronunciation, and script direction provides an indication of the breadth of the types of conventions that cultural communities generate and integrate into their language use. The work also provides a few hints about the consequences of those conventions. Conventions about category relations, for example, end up influencing cooperative group behavior. Linguistic conventions generated by cultural communities are not just resolving ambiguities over reference or providing defaults for coordination. They are also guides for thought and action.

Linguistic Conventions Are Tools for Thinking

The idea that language provides a toolkit for thinking is an old and useful one (Gentner, 2016). The logic is that linguistic conventions provide ways to augment or facilitate reasoning. Obviously, writing something down, so that we no longer have to remember it, is a kind of cognitive tool. There are many ways in which linguistic conventions might foster reasoning, and cultural and linguistic differences in conventions provide one means for identifying them. It is possible to consider some of the conventions just discussed as instances of linguistic conventions serving as tools for thinking. For example, metaphor choice implies making a metaphor conventional, which can then serve to guide reasoning. But if we step back to consider what a tool for thinking might do, we have two main options. Information-processing systems can be described at a high level as consisting of information and processes acting on that information. Accordingly, linguistic conventions can serve as tools by fostering the ease of processing or by fostering the development of information.

Processing Ease

Some tools are easier to wield than others. Accordingly, conventions have consequences, because they might foster ease of processing and thereby foster thinking. The classic example here is the case of words for numbers. Shorter words provide an advantage in maintaining content in short-term memory, and because Chinese words for numbers tend to be shorter than English words for numbers, Chinese speakers tend to have longer digit spans than English speakers (Stigler, Lee, & Stevenson 1986). Digit span, in turn, is associated with arithmetic performance (Geary, Bow-Thomas, Liu, & Siegler, 1996; see also Imbo & LeFevre 2009). The suggestion is that conventions that economize or otherwise fit with our processing tendencies are going to provide support for thinking.

That notion of fit with our processing tendencies is central to the underlying logic of studying culturally prevalent information to look for recurring qualities. For example, studying traditional oral narratives shows a wide array of conventions, many of which address challenges to remembering large amounts of information, such as repetition, meter, rhyme, motifs, and so forth (Rubin, 1995). Schematic plot structures can also become conventional because they map onto typical causal patterns, or because they foster learning. For example, the three little pigs story, MasterCard's "Priceless" advertisements, the main motif in Beethoven's fifth symphony, and many common jokes all rely on repeating highly similar elements to encourage comparisons. This leads to forming an expectation that can then be violated to generate surprise. It is a plot structure that is a recipe for surprise, and as a result seems to be widespread in cultural narratives around the world (Loewenstein & Heath, 2009; Loewenstein, Raghunathan, & Heath, 2011). Conventions can form with a range of fits to processing ease. While it might seem that those that fit are more likely to survive and spread, there are plenty of examples of enduring misfits.

To pick just one example, while in English 42 is said "forty-two," in German the convention is inverted; one says, in effect, "two and forty." As a result, German-speaking children tend to make inversion errors (e.g., mixing up 42 and 24; Zuber, Pixner, Moeller, & Nuerk, 2009). These kinds of effects hold for speakers even when they just have to select which of two numbers (e.g., 42 or 15) is larger, and cross-linguistic differences in errors

are notable only when the inversion matters (42 or 15, but not 21 or 45; Pixner, Moeller, Hermanova, Nuerk, & Kaufmann, 2011). Consequently, conventions can support or hinder the ease of processing information.

Tagging and the Development of Information

Linguistic conventions can serve as tags. Some kinds of items in the world are fairly well individuated by our perceptual systems (Spelke, 1990). We can pick up and throw a ball, which we can then observe moving. But perceiving items is not enough, as we need to refer to them when communicating with others, and we need to coordinate with others about them. It helps if we can tag them in some way and thereby mark out something in the world. Tagging provides the basis for individuating items, for making distinctions between items, and so for forming dimensions and categories.

The particular term, *tag*, is drawn from an argument about the fundamental role of making marks for individuating and aggregating items in complex adaptive systems (Holland, 1995). There are related arguments in work on the nature of symbol systems (Peirce, 1974). To these, language acquisition research added the social imperative aspect (Brown, 1958): that one person tagging something had implications for others, because it is a social communication with its attendant pragmatics (Grice, 1989). Words can mark out proper names for individuals (Rips, Blok, & Newman, 2006), word use can serve as directives to form categories (Waxman & Markow, 1995), and words can identify nonobvious patterns (Gentner, 2010). But to do any of these things, words first have to be present as a marker or tag.

This idea of words as tags is a somewhat different approach to thinking about word use than is often taken. For example, a robust theme in language acquisition research is to identify the heuristics and assumptions that language learners appear to make about what new words mean (e.g., Markman, 1989) and to identify ways in which learners differ due to differing conventions coming from their languages (e.g., Imai & Gentner, 1997). But there is also an ongoing debate about whether words are special or whether they are just another feature (e.g., Mayor & Plunkett, 2010; Sloutsky, 2015; Westermann & Mareschal, 2014). One possible resolution is that words are context-general discrete tags that can take on particular

importance for being part of a system (cf. Dotan & Dehaene, 2016; Edmiston & Lupyan, 2015; Loewenstein et al., 2012). Once there is a semiotic system for marking out individuals and aggregates, specific examples and categories, and that system is conventionally used, then the community can develop information collectively.

For example, learning to make and use distinctions in how we encode what we perceive leads to becoming more sensitive to the dimensions that are key to defining and segmenting examples with different tags (Goldstone, 1994). Put another way, using language requires learning and applying conventionally distinguished categories and so requires acquiring sensitivity to distinctions necessary for separating those categories (Majid, Jordan, & Dunn, 2015). To take a specific case, Japanese speakers often follow conventions requiring them to distinguish the relative ages of the people with whom they are speaking, whereas Italian speakers do not have such conventions. When presented with information that was purportedly said by someone just older versus just younger than themselves, Japanese speakers were more accurate than Italian speakers at recalling who said what (Karasawa, Maass, Rakić, & Kato, 2014). No such differences were found when the speakers were described as both being older or both being younger, or when the numbers representing age were instead described as favorite numbers. This pattern is consistent with the idea that Japanese conventions to attend to relative age led to attending to and using that information to bolster memory.

There are countless distinctions around which languages generate conventions, and so many ways in which this informational aspect of conventions can be a tool for thinking. As a different kind of example, Turkish is one of a number of languages that require speakers to use a grammatical marker to distinguish whether they perceived something directly or learned of it indirectly. There is some evidence that Turkish preschoolers tend to be developmentally advanced on false belief and selective trust tasks, relative to Chinese and English preschoolers (Lucas, Lewis, Pala, Wong, & Berridge, 2013), and the linguistic conventions could account for that trend.

A further set of findings highlights the role of language in generating coarser and finer grained distinctions in an entire domain of meaning. For example, Dutch distinguishes support from below (*op*), vertical attachment

(*aan*), and containment (*in*), whereas in English the first two are called “on” and the last one is called “in,” and in Spanish all of them are called *en* (Bowerman, 1996). The particular conventions for encoding spatial relations seem to guide spatial reasoning. For example, preschool children who watched a toy being hidden under one of several items on a table, then moved to a different position around the table before retrieving the toy were more likely to accurately retrieve the toy when given a verbal description with spatial terms rather than no verbal description or just pointing (Miller, Patterson, & Simmering, 2016). As a further example, after being shown three different toys in a line, and then turned 90 degrees and asked to set up the same three toys so they matched, Dutch children put the toys together in the same orientation relative to themselves, whereas Namibian children put the toys together in the same orientation relative to cardinal directions (Haun, Rapold, Janzen, & Levinson, 2011). Languages that conventionally use cardinal directions (north, south . . .) rather than relative directions (left, right . . .) can even use this spatial relations framework as a metaphor to structure their views of time and how they conceptualize orderings of events (Boroditsky & Gaby, 2010). Conventions instantiated in language that mark spatial relations distinctions, and distinctions more generally, are a way of developing particular perspectives and particular expertise.

A similar sort of system of distinctions instantiated by convention in language can be found in the domain of smell. Although English and many major Western languages have quite modest vocabularies for odors and rely predominantly on metaphor to describe odors, there are languages with much richer vocabularies. The rough idea can be captured with an analogy to color: that rather than describing colors with metaphors (“like the sky on a sunny day”), we can describe colors with specific color words (*blue*). So it goes with odors as well. For example, the language Maniq has a lexicon of about 15 odor words that appear to be organized around two main dimensions, pleasantness and dangerousness (Wnuk & Majid, 2014). This might indicate a coherent semantic system for odor. Having a coherent odor vocabulary makes describing examples efficient. Whereas American speakers of English can efficiently code color in examples, they are unable to do so for odors; speakers of Jahai can efficiently code both color and odors in examples (Majid & Burenhult, 2014). Thus, language conventions can

make entire domains of meaning more or less tractable by offering or not offering systems of distinctions.

Systems of distinctions matter over and above making any particular distinction. As suggested in the work on spatial prepositions, multiple distinctions often work together to segment a domain of meaning. They can then be used together to interpret situations. For example, while independent spatial terms provided some support to preschool children in performing a spatial mapping task, a system of spatial terms led to still higher performance (Loewenstein & Gentner, 2005). Or, adults taught quilting vocabulary, as opposed to quilt histories, were more likely to infer additional distinctions and use both the explicitly trained and the inferred distinctions to form preferences, and to do so more quickly and stably (West, Brown, & Hoch, 1996).

In summary, there are three main implications of tagging. The first is that conventions can foster learning and using particular tags that make particular distinctions, as with the example of Turkish just noted. The second is that languages can form tagging conventions with different degrees of complexity and detail, as with the examples of space and smell. The third is that languages can form systems of tagging conventions that can then be used together to guide thinking and behavior, as with the example of quilting terms and spatial relations systems. Thus, tagging conventions are a form of collectively generated information that is then available to, if not mandatory for, guiding thinking and behavior.

Linguistic Conventions Are Tools for Social Influence

The discussion of linguistic conventions as tools for thinking emphasizes the effects on individuals, but looked at from the other direction, nearly every behavioral study is also a study of social influence. For example, nearly every category learning study is described as a test of individual cognitive processing, but it could also be described as social entrainment: Can individuals be guided to respond in a specific way? Language, as Lupyan and Bergen (2015) emphasize, is not only a communication system but also a control system. There are first-order controls of direct observation and feedback, second-order controls of routines and standard operating

procedures, and third-order controls of premises and taken for granted beliefs (Perrow, 1986). Culture relies on language as a primary deliverer of second- and third-order controls. We instruct others, and so we program others.

Language as a form of social influence is foundational to thinking about how culture shapes behavior. Learning from others is foundational, because it is a low-cost, high-value means for identifying how to navigate a complex world (Boyd, Richerson, & Henrich, 2011). Cultural learning is most powerful when it offers integrated systems of knowledge that can accumulate and develop over time and across generations (Boyd & Richerson, 2005), as language so clearly fosters. And the induction problem of learning language for coordination with others (we all try to do the same thing) is arguably easier than the induction problem of learning language to model the world (we try to do the right thing based on understanding the world accurately; Chater & Christiansen 2010). Consequently, linguistic conventions are integral to foundational aspects of cultural accounts.

Accounts of culture that do not explicitly make linguistic conventions central nonetheless seem to rely on them implicitly for a good deal of their power and reach. For example, the dynamic constructivist approach to culture (Hong, Morris, Chiu & Benet-Martinez, 2000; Hong & Chiu 2001; see also Leung & Cohen, 2011, for a related approach) characterizes culture as providing bundles of knowledge and styles, which people are prompted to apply based on cues in situations. Language has long been noted to be one such cue (Bond & Yang, 1982). Language is also important to generating and disseminating the knowledge and styles. And language is important for distinguishing kinds of situations.

These are large-scale kinds of social influence. The reason linguistic conventions are a widespread form of social influence is because language is not just a tool for individual thinking. As Putnam (1973) argued, language is a tool less in the sense of a hammer or a saw and more in the sense of a steamship or an airplane. It is a collective tool. We do not generate, use, or change these tools by ourselves. We can use them, indeed, organize important aspects of our lives around them, even play a critical niche role in their use, without much understanding of them. The mechanic who fixes the plane need not be able to fly the plane. The passenger need have no ability to do either. Similarly, we can use words like *heart attack*, *pinot noir*, and so

forth, without any ability to identify what is and is not a member of the category or to know what makes something a member of the category. Consequently, linguistic conventions are a particularly powerful form of social influence, because people rely so heavily on them, take that reliance for granted, and generally abide by a host of conventions, with little awareness of doing so. And as indicated in the prior discussions, relying and using conventions have consequences.

Linguistic conventions are an opportunity for connecting individual psychology to large-scale social and cultural patterns. For example, using first-person plural pronouns (e.g., *we* or *us*) tends to foster a collectivist orientation, whereas using first-person singular pronouns (e.g., *I* or *me*) tends to foster an individualist orientation (e.g., Brewer & Gardner, 1996). The reverse is also the case; the orientation leads to the pronoun pattern (Na & Choi, 2009). It is therefore of interest that American books (Twenge, Campbell & Gentile, 2012) and Chinese books (Hamamura & Xu, 2015) in the past 40 years show substantial increases in first-person singular pronoun use, suggesting a rise in societal individualism. Matching micropatterns with macrotrends indicates that linguistic conventions may provide a mechanism by which large-scale social tendencies can be instantiated in specific situations and so influence specific individuals.

There is an opportunity to push on that connection more than has been done thus far. For example, the earlier work on abstraction found different conventions among Italian and Japanese speakers in their use of abstract descriptors for people (Maass et al., 2006). There is also a cultural difference in attribution patterns toward people versus situations. It is possible that the linguistic conventions around level of abstraction play a role in maintaining those attribution patterns. One result would be linguistic conventions that reinforce stereotypes—not only particular stereotypes but also the tendency to rely more versus less heavily on stereotypes generally. There are many more patterns about which we can only speculate. For example, polite language appears to encourage adopting a distant construal, and adopting a distant construal appears to encourage using polite language (Stephan, Liberman, & Trope, 2010). Perhaps cultural conventions about how often to use polite language might help engender chronic construal levels at a societal level.

On the flip side, there are intriguing macrolevel patterns that merit more microlevel support. For example, product names can signal hard to observe properties, or even add such properties, and so be instrumental in guiding or generating appeal. In a study of reviews of over 18,000 beers made in the United States, those with names with anti-mass-production references (e.g., “Morgantown Brewing Company’s *Small Batch*-Honey Raspberry Amber Ale”) tended to attain greater ratings, although no such advantage was found for beers with these names in blind taste tests (Verhaal, Khessina, & Dobrev, 2015). Or there are debated cross-linguistic macrolevel data suggesting a link between linguistic conventions around marking future actions and behavior patterns around saving (Chen, 2013) that are in need of testing at the microlevel. It is possible that there is a link between how a language encodes time and how people make decisions about the future, but the number of possible artifacts is sufficiently large that direct microlevel testing is more likely to be fruitful.

There are also important macropatterns to study for their own sake. For example, tracing linguistic conventions can reveal community-level influence. A study of business jargon revealed that academics pick up more practitioner terminology than the other way around (Barley, Meyer, & Gash, 1988). A similar logic is behind looking at translation patterns from one language to another to identify that some languages are hubs from which many other languages borrow words, ideas, cultural products, and more. Names of famous people in hub languages, for instance, tend to become known in other languages more than the reverse, indicating what are likely pervasive effects of hub cultures on other cultures (Ronen et al., 2014). One question along these lines is whether to be concerned about the dominance of the English language in global business, science, and other fields. For example, it is increasingly difficult in some areas of science to engage in informed inquiry in languages other than English, because all the technical terminology is in English.

Far more research is needed on the role of linguistic conventions in large-scale social influence, because it is likely central to understanding political power. Mass media make linguistic conventions easier to establish than ever, as communications now have such broad reach (e.g., Fusaroli et al., 2015). The impact of linguistic conventions is effectively global.

The stakes for understanding the role of conventions on large-scale social outcomes could not be higher. Media can make social classifications with an unappealing identity conventional, allowing for later dehumanizing classifications and in turn providing a basis for popular support of conflict and genocide (Donohue, 2011). As noted earlier in the work on essentialism, establishing negative attributions with generic language and so indicating that negative aspects are part of the very identity of a social community sets the stage for social conflicts. Even simple exposure to biased labels in media communications has been linked to increased ingroup favoritism (Fasoli, Maass, & Carnaghi, 2015). It gets worse. Leaders' communications of contempt, disgust, inferiority, and intolerance have been associated with followers' later acts of aggression (Matsumoto, Hwang, & Frank, 2013). Disease fears stoke antioutgroup action, laying the groundwork for social conflict (Dutta & Rao, 2015). Understanding how to establish and change linguistic conventions, given their potential for influence on action within and across cultural communities, is more pressing than ever.

DISCUSSION

Understanding culture involves understanding how we form collective meanings, practices, or values. For such things to be collective requires consistencies in thought and behavior. To generate such consistencies, language plays a prominent role, because it is a widespread system for coordination. It is for this reason that linguistic conventions, rather than words, syntax, pragmatics, categories, cognition, or a host of other possibilities, provide a useful (but underused) starting point for examining language and culture.

Starting with linguistic conventions solves a few problems and raises a few new avenues for exploration relative to most prior work on language and culture. Rather than invoking mysterious versions of collective minds, we can examine the social processes of forming conventions that individuals observe, draw inferences from, coordinate around, teach, sanction others for violating, and so on. Cultural research can benefit from being sensitized to various types of local community cultures. In addition to societal cultures, we also have regional cultures, urban cultures, professional cultures,

organizational cultures, and more. Linguistic conventions are pointers to identifying them and to understanding them. Similarly, languagewide conventions are not the only conventions of interest. Localized conventions related to particular semantic domains, situations, or speakers are also of importance.

Focusing on linguistic conventions provides a different view of some long-standing proposals. For example, if language is a collectively generated, constantly changing, system of cultural conventions, then it does not make sense to ask whether language determines thought. That proposal relies on reifying and essentializing language, and on confusing different levels of analysis. Instead, it might be stimulating to remember the ways in which language is like deciding that in this game, the stick is a microphone and the rubber band is a crown, forgetting tomorrow that it was not always so, and teaching it the next day to someone else who never knew it was otherwise. Then we can consider assessing consistencies and differences in how and when individuals understand and abide by conventions, and in what assumptions they take for granted. We have to rely on what we know, and it is easy to forget that part of what we know is stuff we just made up.

Focusing on linguistic conventions provides new reasons to examine variability. Collective meanings, practices, and values are ideal types, with idealized essences and definitions. Who believes, does, and feels what will vary. People vary because of the degree to which they are familiar with and a part of their communities. They vary because of the degree to which they abide by or assimilate their community's conventions. They vary because of their memberships in multiple communities (Morris, Chiu, & Liu, 2015a). Mass communications, events that are widely attended, opportunities to interact repeatedly, large-scale cultural logics about conformity and other such forces will presumably foster consistency and likely yield larger, more detailed, and more systematic collections of conventions (Gelfand, Nishii, & Raver, 2006). The opposites, as well as inevitable changes in technologies, products, and the historical events people experience, will presumably foster inconsistencies and fragmentation. Rather than essentializing collective meanings, practices and values, we could estimate their variability in adoption and interpretation.

In studying variability, we could do more to study differences in depths of understanding and degrees of power over linguistic conventions. Beyond

examining behavior in specific situations and languagewide conventions, it is also useful to examine different roles within cultural communities. What are the means by which conventions can be generated, changed, and discarded? What are the means by which systems of conventions can be made more coherent, merged with other systems, or be broken and refashioned? There are starting points for addressing such questions (e.g., work on vocabulary structure and communication types; Ocasio, Loewenstein, & Nigam, 2015), but there is less on the particular kinds of roles individuals can play in these processes. If linguistic conventions are collective tools, like steamships and airplanes (Putnam, 1973), then understanding what it means to be passengers, pilots, or maintenance workers becomes an opportunity for study.

To do those studies, we will need to be as inventive as the studies reviewed. Linguistic conventions are not only about what is written on the page but also about how language links to socially coordinated experiences. The rise in sophistication of text analyses is exciting, but it has come along with a strong focus on written text, to the exclusion of all other aspects of language. The histories of perceptual, motivational, affective, physical experiences are missing. Raising attention to linguistic conventions is not an invitation to isolate language from the rest of cultural activity.

In conclusion, we can view language as a tagging system that members of cultural communities use to generate and distribute information so as to coordinate their behavior, or even as a tagging system that allows people to coordinate their behavior, allowing for the formation of stable, cumulative, widely dispersed cultural communities. Regardless of whether language or culture is seen as primary, though, systems of linguistic conventions generate information from which we derive the meanings that we use to make sense of our experiences and so our lives. But even more than that, we use language and develop language and refashion language as we engage with others and with the world. As a result, we can view language as a ubiquitous tool for generating massive, intricate, distributed systems of conventions. We then use these linguistic conventions to coordinate our behavior, to work together, to engage with one another, and to create much larger and more encompassing cultural worlds than we could otherwise. As Toni Morrison put it in her Nobel lecture in 1993 upon receiving the prize

for literature: “We die. That may be the meaning of life. But we do language. That may be the measure of our lives.”

CHAPTER 10

Culture and Motivation

Heejung S. Kim and Smaranda I. Lawrie

Recent theorizing in cultural psychology posits that culture develops in response to the pressures and needs posed by physical and social environments as a way to increase a group's chances of survival. Reflecting this perspective, we theorize that local environmental demands shape cultural goals that, in turn, loosely foster culture-specific patterns of actions and interactions. In this chapter, we first review the literature connecting cultural characteristics to environmental demands. Based on this review, we propose four cultural goal orientations that vary across cultures: shared versus personal goals, instrumental versus emotional goals, adjustment versus expression goals, and avoidance versus approach goals. Subsequent sections of the chapter describe how these cultural goals shape neural and genetic processes and motivate a wide range of psychological and behavioral processes such as health behaviors and academic and organizational behaviors. In the second half of the chapter, we discuss how cultural goals motivate relationship processes such as relational mobility, social support use, and prosocial behaviors. In so doing, we aim to highlight that a full understanding of human behaviors begins with the consideration of particular demands posed by ecological and historical environments and that the investigation of cultural influence requires contextualizing individuals in their relationships, the primary conveyers of cultural patterns of psychology and behaviors.

Human behaviors are composed of many ingredients. In the study of human behavior, the understanding of motivation occupies a central position because it is the ingredient that provides insights for *why* people do what they do. Motivation is the direct force that propels individuals to act toward specific goals. Not surprisingly, psychologists have always been interested in motivations and motives. How to make an organism act, and act faster and

better, was one of the first questions of social psychology (Triplet, 1898), and it remains a key question (e.g., G. Cohen & Sherman, 2014). Psychologists often grapple with understanding the primary reasons for human behavior, and theorists have proposed a number of basic motives, including belonging, self-worth, and control (e.g., S. Fiske, 2009; Kenrick, Griskevicius, Neuberg, & Schaller, 2010). A quick Internet search suggests that the largest number of proposed basic motives is 16, and once basic biological needs are accounted for, the number typically comes down to five or so. Whether one agrees with any given list of basic human motives, a couple of clear inferences can be drawn from this exercise. One inference is that few psychological motives are universally shared. The second is that the most commonly identified basic psychological human need is the need to belong, also known as the “belongingness motive” (e.g., Baumeister & Leary, 1995; S. Fiske, 2009; Kenrick et al., 2010).

These two inferences draw attention to the prominent role of culture in shaping and diversifying the primary motives that underlie human behavior. Culture develops in response to the pressures and needs posed by physical and social environments as a way to increase a group’s chances of survival (e.g., Chiao & Blizinsky, 2010; Fincher, Thornhill, Murray, & Schaller, 2008). Specific motives fostered at the cultural level therefore vary depending on the times and where cultures are located. Once these motives are formulated, they provide the framework people use to make interpretations, judgments, and decisions (Bruner, 1990; Geertz, 1973; Shweder, 1995). Successful learning of these motives is therefore likely to impact both the likelihood of belonging and one’s chances of survival. In this chapter, we first outline the literature connecting cultural characteristics to environmental demands. Then, based on this review, we identify a set of culturally varied goal orientations. We then outline in subsequent sections of the chapter how these cultural goals motivate a wide range of psychological, behavioral, and relationship processes.

Although we use classic works in cultural psychology as springboards, we focus the bulk of our attention on recent progress in the field. During the last decade, research has advanced in cultural psychology in both breadth and depth, particularly in four general directions. First, beyond identifying basic psychological processes, notable advances have been made in how knowledge about cultural differences in motives and goals might be utilized

in socially relevant domains such as health behaviors and education. Second, remarkable progress has been made in cultural neuroscience. Third, the notion of culture has been broadened to include other social categories such as religion and social class (e.g., A. Cohen, 2009). Fourth, recognizing that one of the main pathways of cultural influences is interpersonal, researchers have begun investigating how culture influences relationship processes (e.g., Adams & Plaut, 2003; Kim, Sherman, & Taylor, 2008; Yuki & Schug, 2012). We have structured the chapter first to review research findings that show how cultural motives shape individual goals, then move on to describe research on culture and relationship goals. In this latter section, we discuss how models of relationships both reflect cultural motives and function as the main carrier of cultural worldviews and expectations.

WHY DO CULTURAL MOTIVES VARY?

Although there are many needs shared among all humans, different physical, social, and historical environments determine the priority of needs and demand the achievement of certain goals over others. With the necessity to overcome challenges that are more immediate or severe, certain demands that are more essential in a given environment may become primary over other demands. Psychologists have started to recognize the role of social ecology in the shaping of psychology, and this perspective holds particularly important implications for cultural psychology (see Talhelm & Oishi, [Chapter 4](#), this volume). Extending the questions of cultural psychology to probing the origins of cultural diversity, a number of prominent theories have been proposed to explain cultural orientations such as individualism–collectivism, independent–interdependent self-construals, or analytic–holistic cognitive styles (Chiao & Blizinsky, 2010; Fincher et al., 2008; Kitayama, Ishii, Imada, Takemura, & Ramaswamy, 2006; Talhelm et al., 2014; Uskul et al., 2008). These theories propose ecological and social-historical factors, such as prevalence of pathogens in the environment (Fincher et al., 2008), history of voluntary settlement (Kitayama et al., 2006), or primary modes of subsistence (Uskul et al., 2008), that necessitate social interdependence or promote independence, which in turn form the bases of

individualistic and collectivistic cultural orientations across different regions of the world.

Regional differences are not the only source of differential environmental pressures. Other sociocultural factors, such as social class and religion, also shape demands and shift priorities of needs. The working-class context tends to present fewer material and financial resources. Consequently, social networks become a more important resource in the working-class context, thus fostering more interdependent views of the self compared to middle-class contexts in which social networks are less vital to survival (Stephens, Fryberg, Markus, Johnson, & Covarrubias, 2012; Stephens, Markus, & Townsend, 2007). Religion¹ also increases interdependence by fostering a sense of community within religious groups (Graham & Haidt, 2010; Norenzayan & Shariff, 2008). These examples illustrate the role of environmental demands in shaping the needs that are prioritized in a given local context. Once set, these needs shape specific sets of values, worldviews, and culturally shared patterns of behaviors and interactions (A. Fiske, Kitayama, Markus, & Nisbett, 1998; Kim & Markus, 1999; Kitayama, 2002).

CULTURAL DIVERGENCE IN PRIMARY GOALS

By providing the theoretical framework to understand cultural diversity, the characterization of cultures based on the individualism–collectivism value dimension (Hofstede, 1980; Triandis, Bontempo, Villareal, Asai, & Lucca, 1988) and independent–interdependent self-construals (Markus & Kitayama, 1991) has been responsible for culture becoming a mainstay in psychology. These approaches have inspired a tremendous amount of research investigating the influence of culture on just about every aspect of human psychological processes. How individuals are considered to be connected to their groups forms a basic and fundamental perspective to think about the world and a person's place in it, and individualism–collectivism is considered the most important cultural value dimension (Triandis et al., 1988).

“Individualism,” as a cultural value dimension, refers to the tendency to prioritize the needs of the individual over those of the group, whereas

“collectivism” refers to the tendency to subordinate the individual’s needs to those of the group (Triandis, 1989). “Independent self,” commonly found in individualistic cultures such as those of North America and Western Europe, and especially among the middle and upper class, refers to the view of personhood as an independent, self-contained, autonomous entity that comprises a unique configuration of internal attributes that propel behaviors (Markus & Kitayama, 1991; Oyserman, Coon, & Kimmelmeier, 2002). In contrast, “interdependent self,” commonly found in collectivistic cultures such as those found in many parts of East Asia, Latin America, and Africa, as well as among the working class and the religious, represents a view of personhood as being fundamentally connected with others, inseparable from the social context, and centrally motivated by external and social factors such as social fit and fulfillment of obligations (Markus & Kitayama, 1991; Oyserman et al., 2002).

Countless empirical studies have demonstrated the wide and deep influence of these values and self-construals across myriad psychological processes associated with attention, perception, emotion, cognition, and motivation. Taken together, these studies present a diverse and complex picture of collectivistic and individualistic ways of living. As a field, cultural psychology now knows that personal happiness (e.g., Oishi, Diener, Lucas, & Suh, 1999; Suh, Diener, Oishi, & Triandis, 1998) and high self-esteem (Heine, Lehman, Markus, & Kitayama, 1999; Kitayama, Markus, Matsumoto, & Norasakkunkit, 1997) are easier to achieve, but perspective taking (Wu & Keysar, 2007) and contextual thinking (Masuda & Nisbett, 2001) are harder to develop in more individualistic cultures. Cultural psychologists also know that in more collectivistic cultures, self-adjustment/self-regulation (Morling, Kitayama, & Miyamoto, 2002; Seeley & Gardner, 2003) and enduring, less-mobile relationships (Schug, Yuki, Horikawa, & Takemura, 2009) are more commonly exercised, but generalized trust (Adams, 2005; Yamagishi & Yamagishi, 1994) and emotional support are less common (J. Chen, Kim, Mojaverian, & Morling, 2012; Kim et al., 2008). It is also increasingly clear that collectivism and individualism manifest differently in various parts of the world because cultures cannot be explained by a single value dimension (Schwartz, 1990). Rather, significant ranges of behavioral responses are observed in both

collectivistic and individualistic cultures (Campos & Kim, 2017; Glazer, 2006).

Integrating the social-ecological perspective with accumulated knowledge about cultural orientations, it is evident that psychological and behavioral characteristics associated with cultural orientations (e.g., individualism and collectivism) are highly functional adaptations to social, historical, and physical environments. Thus, these orientations easily translate into fairly concrete cultural goals. Indeed, we argue that cultures vary in their primary goals, at least loosely, according to these social orientation dimensions. Based on our review of the existing literature, we observe that there are broadly four goal orientations that vary across cultures with collectivistic or individualistic orientations: shared versus personal goals, instrumental versus emotional goals, adjustment versus expression goals, and avoidance versus approach goals.

Shared versus Personal Goals

In more collectivistic cultures, social processes are especially geared toward meeting shared social goals, whereas in more individualistic cultures, they are geared toward meeting individual goals (C. Chen, Chen, & Meindl, 1998; Markus & Kitayama, 1991). As a matter of fact, prioritizing group goals over individual goals is one of the core distinctions between collectivistic and individualistic cultures (Triandis, 1989). East Asians, for example, are more motivated to employ a cognitive dissonance reduction process when the relevant actions involve others (e.g., making choices for others) than when the actions involve only themselves (e.g., making choices for oneself), whereas European Americans show the opposite tendencies (Heine & Lehman, 1997; Hoshino-Browne et al., 2005; Kitayama, Snibbe, Markus, & Suzuki, 2004). Social loafing is also less pervasive in more collectivistic cultures than in more individualistic cultures (Karau & Williams, 1993), and a close other's involvement in decision making increases motivation among Asian American children, whereas personal decision making increases motivation among European American children (Iyengar & Lepper, 1999).

Instrumental versus Emotional Goals

Collectivistic cultures prioritize goals to maintain harmonious but not necessarily emotionally positive social ties because social relationships serve as instrumental and pragmatic resources in these contexts (Adams, 2005; J. Chen et al., 2012; Kim et al., 2008; Snibbe & Markus, 2005). Based on social-ecological theories, which propose that cultural characteristics are responses to environmental demands, we infer that the centrality of social relationships common in collectivistic cultures is by and large instrumental in nature because reliance on others is a prerequisite for one's survival and thriving in these contexts (e.g., historically farming regions or working-class contexts). Therefore, we reason that as long as one's role and position in the social network is secure, feeling positively, in general and toward oneself, is not a central goal in these cultures (Heine et al., 1999; Suh et al., 1998).

In contrast, in environments in which an individual's survival and thriving do not depend on social relationships to the same extent, the instrumental function of social relationships is diminished, and the salience of the emotional function of relationships increases. Consequently, individualistic cultures tend to prioritize goals to maintain relationships that serve as emotional resources (e.g., Gable, Gonzaga, & Strachman, 2006; Maisel & Gable, 2009), and the affective and emotional aspects of social processes are highlighted. This emphasis on emotional well-being also ties in with other well-documented cultural goals in more individualistic cultures; both self-enhancement (Heine et al., 1999; Heine & Hamamura, 2007) and life satisfaction depend strongly on the experience of positive emotions (Suh et al., 1998).

Adjustment versus Expression Goals

European Americans are highly motivated to express their thoughts and emotions, whereas East Asians are less motivated by expression goals (e.g., Butler, Lee, & Gross, 2007; Kim & Sherman, 2007; Matsumoto, Yoo, & Nakagawa, 2008). Because more individualistic cultures allow people to consider social relationships as more than a resource essential for survival, motives related to an individual's personal desires and the expression of

thoughts and emotions become more central determinants of behavior (Kim & Sherman, 2007; Kim, Sherman, Ko, & Taylor, 2006; Snibbe & Markus, 2005). Furthermore, because people's behaviors are assumed to correspond with their thoughts and feelings (Choi, Nisbett, & Norenzayan, 1999; for social class differences, see Kraus, Piff, Mendoza-Denton, Rheinschmidt, & Keltner, 2012), inconsistency between thoughts and behaviors causes dissonance (Heine & Lehman, 1997; Hoshino-Browne et al., 2005; Kitayama et al., 2004), whereas opportunities to express personal thoughts and feelings affirm the self (Kim & Ko, 2007). In collectivistic cultures, in contrast, one's self-worth is evaluated by how well one functions as a member of a group (Heine et al., 1999). The goals of fitting in and aligning oneself with situations are therefore emphasized (e.g., Morling et al., 2002). Thus, rather than reflecting one's inner thoughts, values, and preferences, behaviors are often influenced by social demands and expectations (e.g., Reimer, Shavitt, Koo, & Markus, 2014).

Approach versus Avoidance Goals

One implication of considering social relationships as a crucial and instrumental resource for survival is that one has to be more aware and mindful of others' evaluation of oneself and its consequences. In more collectivistic cultures, where a person's primary concern is to navigate the established social network successfully, other people's harmful evaluation of oneself is likely to be highly costly, and the potential cost of failure could have a stronger implication than the potential gain from success. In other words, by psychologically privileging others' perspective over their own, people in more collectivistic cultures may place themselves in a state akin to a powerless psychological state, which in turn fosters an inhibition system (Keltner, Gruenfeld, & Anderson, 2003). Therefore, we propose that avoidance goals are generally more central than approach goals. In contrast, approach goals take priority in more individualistic cultures (Elliot, Chirkov, Kim, & Sheldon, 2001; Lee, Aaker, & Gardner, 2000; Hamamura, Meijer, Heine, Kamaya, & Hori, 2009). Consequently, among people with an interdependent self-construal, failing at a task triggers the motivation to improve more than succeeding on a task does, whereas among people with

independent self-construals, success triggers motivations to excel and distinguish oneself (Heine et al., 2001).

Using these four goal orientations as a guide, we review research findings that show concrete psychological and behavioral consequences in both personal (or intrapersonal) and relational (or interpersonal) behavioral domains. The review is organized into sections focusing on specific research topics such as health communications and social support use, within which we address how cultural goal orientations explain relevant findings.

CULTURAL GOALS AND IMPLICATIONS FOR INTRAPERSONAL PROCESSES

In this section, we focus our review on how cultural goals influence individual motivations in terms of willingness to act, willingness to change or maintain actions, and psychological reactions to these actions. We draw on evidence from studies employing diverse methodological approaches and cover findings from research in cultural neuroscience, health communications, academic and organizational behavior, and choice and decision making.

Cultural Neuroscience

The field of cultural neuroscience has grown rapidly in the last decade (Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume). Although technically a methodological approach rather than a content area, the literature often treats the field as such, probably because it is a relatively young field. Following suit in this section, we combine research findings utilizing neuroscience methodology, regardless of the psychological domains of interest. Much of the empirical evidence from cultural neuroscience contributes to the understanding of basic neural processes underlying previously documented culture-specific patterns of behaviors and psychological processes. These studies generally confirm the previous behavioral findings at the neural level, thus providing information about not only psychological but also biological underpinnings of these phenomena.

Shared versus Personal Goals

Cultural research with a neuroscientific component has shown that given the importance of others in goal pursuit, being misjudged by close others has a detrimental effect on motivation for Asians and Asian Americans, whereas the same felt misunderstanding does not impact motivation for European Americans (Lun, Oishi, Coan, Akimoto, & Miao, 2010). These results were found in participants' electroencephalic (EEG) response, specifically in the prefrontal asymmetry of alpha power (pFA), a neural indicator of motivational states (Lun et al., 2010). In response to felt misunderstanding, Asians, who see it as a sign of social disconnection, showed greater right lateralization of prefrontal activity, indicating withdrawal and demotivation, whereas European Americans, who see it as a challenge to one's own perspective that can be overcome, showed relatively greater left prefrontal activity, indicating an approach-related motivational state (Coan & Allen, 2003).

Activation of independent or interdependent self-construals also impacts how people respond, on the neural level, to receiving a monetary reward themselves or vicariously watching a friend receive a reward. In one study, priming interdependent self-construals resulted in equal activation of the bilateral ventral striatum (vSTR), a region associated with personal rewards (e.g., Bjork & Hommer, 2007), in response to both personal rewards and vicarious rewards. In contrast, priming independent self-construals activated greater bilateral vSTR responses to personal rewards than to vicarious rewards (Varnum, Shi, Chen, Qui, & Han, 2014). Interdependent priming, as compared to independent priming, also activated stronger responses in the right insula (an empathy region) when participants witnessed a friend losing a reward. These studies show that shared goals are secondary motives in individualistic cultures, whereas personal and shared goals are equally dominant motives in collectivistic cultures, and that more personally or socially relevant situations activate motivational states differently at both behavioral and neural levels.

Adjustment versus Expression Goals

Culture has been shown to influence how the brain responds when engaged in emotion suppression. Unlike European American cultures, in which expression is valued, Asian cultures tend to place greater value on the control of emotional expressions (Butler et al., 2007, 2009). In a study (Murata, Moser, & Kitayama, 2013) designed to examine electrocortical responses of emotion suppression, European Americans and Asian Americans were presented with emotionally charged images, with the instruction either to attend to or suppress emotion expression. Focusing on the parietal late positive potential (LPP) of the event-related potential (ERP), an indicator of whether emotional processing is engaged, the study found that Asian Americans showed a decrease of the parietal LPP during emotion suppression compared to when they were instructed to attend to the emotions. Conversely, European Americans did not show any difference with regard to the two sets of instructions. These findings underscore how cultural goals implicate even basic cognitive and neural processes.

Culture also moderates the association between genes and expressive behaviors. The framework of gene \times culture interactions offers an approach to address how genetic and cultural factors interact to shape behaviors. Oxytocin influences empathic accuracy (Rodrigues, Saslow, Garcia, John, & Keltner, 2009). Given that, oxytocin is theorized to be associated with the degree to which individuals learn to engage in culturally normative tendencies via emotional cues displayed by other members of their culture (Kim & Sasaki, 2014). Reflecting cultural differences in expression motives, studies investigating gene \times culture interactions have found that an oxytocin receptor polymorphism (OXTR *rs53576*) is associated with higher emotion expression and lower suppression among European Americans but lower emotion expression and higher suppression among East Asians (Kim et al., 2010; LeClair, Janusonis, & Kim, 2014).

Similarly, religion impacts how genes are associated with expressive behaviors. In a study (Sasaki, Mojaverian, & Kim, 2015) using implicit priming of religious concepts (a method adopted from Shariff & Norenzayan, 2011), European American participants were involved in a situation in which they had a reason to be dissatisfied with an interaction with a confederate. In the control condition, participants with the socioemotionally sensitive genotype (GG genotype of OXTR *rs53576*) were more expressive of their discontent than were participants without the

genotype. However, when primed with religious concepts, presumably activating religious goals of self-adjustment and prosociality, those participants with the GG genotype significantly decreased their expression of discontent, whereas their counterparts, without the GG genotype, did not change their behaviors. This study shows that the expressive behavioral tendency typically associated with a particular genotype may be reversed when a person is in a religious mindset, in which the adjustment goal is prioritized over the expressive goal.

Health Communications

Building on these more basic demonstrations of cultural differences, researchers during the last decade have tested how knowledge of culture-specific ways of thinking may be used effectively to promote motivations to engage in socially and personally desirable behaviors. The starting premise of these studies is that people hold different dispositions or mindsets and that the congruent framing of persuasive messages with these existing tendencies will impact individuals' behaviors more readily than less congruent framing (Aaker & Lee, 2001; Mann, Sherman, & Updegraff, 2004; Sherman, Mann, & Updegraff, 2006) because congruent messages "feel right" (Cesario, Grant, & Higgins, 2004). Applying this idea to the question of cultural congruency, a number of studies have shown that in health communications, the framing of messages in a way that is congruent with cultural goals proves more effective in drawing out the intended behaviors (see Sherman, Uskul, & Updegraff, 2011, for a review).

Shared versus Personal Goals

Health problems, as a potential hindrance to meeting important goals, trigger different types of concerns depending on dominant self-construals. Illness tends to trigger more social concerns (e.g., "being a burden to people who are close to me") for people who hold a more interdependent self-construal but triggers more personal concerns (e.g., "not being able to rely on myself") for people who hold a more independent self-construal (Uskul & Hynie, 2007). Consequently, health messages may be more effective in

motivating targeted behaviors when the potential health risk is framed as a threat to culturally dominant goals. In a set of studies, researchers examined how people respond to an article about the alleged risk of fibrocystic disease from caffeine consumption while they were experimentally primed with either an independent or interdependent self-construal (Uskul & Oyserman, 2010). When the risks were described as personal risks among people with the independent self-prime, they were more likely to accept the information, acknowledge the self-relevance of the risk, and behaviorally reduce caffeine consumption (i.e., choosing fruit candies over coffee/chocolate candies) than when the risks were described as relational risks. The pattern was the opposite for people with the interdependent self-prime. Notably, the effects of the primes were found only when the prime matched the culturally dominant self-construal. Independent self-priming increased the persuasiveness of the message only among European Americans, and interdependent self-priming increased persuasiveness only among Asians and Asian Americans. In other words, cultural primes make the existing culturally dominant self-schemas more salient.

In some cases, however, congruency between persuasive messages and cultural goals may backfire. When the potential risks are too severe, immediate, and self-relevant, people may become too threatened and resort to defensive information processing. This is especially true for European Americans. For example, when culturally diverse groups of sexually active college students read an article describing the risks of AIDS in either personal or relational terms, the opposite of cultural congruency effects was found (Ko & Kim, 2010). In particular, European Americans were more skeptical of the information and less motivated to engage in protective behaviors when the risks were presented as personal. Asian Americans showed a nonsignificant but opposite pattern. However, when European Americans were induced to self-affirm in order to reduce their psychological defensiveness, their skepticism of the personally framed message decreased, and motivation to make positive behavioral changes increased. These findings suggest that when a potential, highly relevant, and immediate risk threatens a culturally dominant goal, this threat may become too much and lead people to reject the health information altogether.

Avoidance versus Approach Goals

Congruency between loss–gain message framings and dispositional avoidance–approach motivation has also been studied extensively (Mann et al., 2004; Rothman & Salovey, 1997; Sherman et al., 2006). Generally speaking, a close match between dispositional orientations and message frames increases the effectiveness of the message. Building on this idea, studies have indicated that the effectiveness of loss and gain message framing in motivating behavioral changes is greater when the frame is congruent with cultural motives. People from independent cultures (i.e., white British) in which approach goals are highlighted tend to be more readily persuaded by gain-framed health messages (i.e., messages highlighting potential gains from engaging in targeted behaviors). Conversely, people from interdependent cultures (i.e., East Asians) in which avoidance goals are prioritized tend to be more readily persuaded by health messages framed in terms of loss (i.e., messages highlighting potential losses from not engaging in targeted behaviors) (Uskul, Sherman, & Fitzgibbon, 2009; for review, see Sherman et al., 2011).

Academic Motivation and Organizational Behaviors

Shared versus Personal Goals

Cultural goals impact academic and organizational motivational processes as well. Studies show that different factors make different people work harder and longer, and culture is a key determinant of what different people find to be more or less motivating. Whether or not one believes that his or her actions and decisions involve close others makes a significant difference. In general, shared goals tend to motivate those with interdependent self-construals, but personal goals tend to be more motivating for those with independent self-construals. In a classic study, Iyengar and Lepper (1999) demonstrated that personal choice, rather than shared choice with in-group members, increases achievement motivation among European American children, but shared choice is more motivating for Asian American children. A more recent set of studies (Fu & Markus, 2014) probing cultural differences in the relationship between mother and child among Asian

Americans and European Americans found similar results. These studies showed that the notion of “controlling” parenting has culturally divergent meanings. European American high school students described their mothers as a source of support, whereas Asian American students described their mothers as a source of pressure and more instrumentally involved in their lives. For example, Asian Americans mothers were described as giving more advice and providing more practical help. Moreover, more involved parenting and pressure were viewed more positively by the Asian American students, and being primed with images of their mother increased their motivation to persist longer on cognitive problems because these tasks were accompanied by interdependent and shared goals (i.e., an image of their mothers working alongside them). In contrast, the same priming decreased task motivation among European American students. These studies clearly demonstrate that social connection and interdependence in the form of shared goals and effort is motivating for those from interdependent cultures, whereas individual pursuit of a goal is more motivating for those from independent cultures.

Whether educational goals are framed as personal or shared also differentially impacts academic motivation for people from different social classes. As noted earlier, the independent self-construal is more prevalent among middle-class Americans, whereas the interdependent self-construal is more prevalent among working class Americans (Stephens et al., 2007; see also Kraus, Callaghan, & Ondish, [Chapter 27](#), this volume). Goals framed as shared and interdependent are thus theorized to be more motivating for working-class Americans, whereas goals framed as personal and independent are theorized to be more motivating for middle-class Americans (Stephens, Fryberg, et al., 2012; Stephens, Hamedani, & Destin, 2014). In certain situations, these social-class-specific goals can clash. American colleges and universities, for example, tend to promote independent learning goals, such as self-expression and leadership, over interdependent goals, such as listening to the opinions of others and collaborative learning (Stephens, Fryberg, et al., 2012, Study 1). Inadvertently, the independent goals, espoused in higher educational contexts, create a mismatch with the primary cultural goals of certain students (i.e., first-generation college students). This “cultural mismatch” increases the challenges and adjustment difficulties that these students have

to face, compared to students with at least one parent with a college education (i.e., continuing generation college students). The cultural mismatch, in turn, has implications for academic performance (Stephens, Fryberg, et al., 2012) and general well-being (Stephens, Townsend, Markus, & Phillips, 2012). More recent research has focused on finding ways to address this problem. Stephens and colleagues (2014), for example, conducted an intervention study in which students were made aware of how their diverse backgrounds may shape their experiences and challenges (difference-education intervention). They found that acknowledging and normalizing this experience of cultural mismatch via this intervention can increase a sense of belonging and attenuate negative impacts. Similarly, representing the learning goals of higher education in language that is more inclusive of interdependent learning goals can also mitigate the negative effects of this cultural mismatch (Stephens et al., 2014).

Differences in the prioritization of shared versus personal goals also have implications in organizational settings. A study with students in China and the United States had participants engage in a negotiation situation in which accountability (low vs. high) and the other party's group membership (ingroup vs. outgroup) were varied. Chinese students downplayed the material aspect of the negotiation in favor of strengthening the relationship. In other words, the Chinese participants took a more prorelationship approach, favoring shared over personal goals (Liu, Friedman, & Hong, 2012; see also Gelfand & Jackson, [Chapter 24](#), this volume). However, this effect was found only when the negotiation target was an ingroup member and accountability was high, that is, when the cultural norm was activated.

Adjustment versus Expression Goals

Previous research has shown that the extent to which people value uniqueness varies across cultures (Kim & Markus, 1999). A recent set of studies (Kinias, Kim, Hafenbrack, & Lee, 2014) probed the underlying psychological mechanism for this previously observed difference. These researchers found that East Asians negatively evaluated a potential hire who displayed non-normative behaviors (e.g., being a vegetarian, being left-handed, or even being unusually friendly), avoided interacting with these

targets, and made negative hiring decisions based on this information. European Americans, however, did not differentiate their evaluations based on these characteristics. More importantly, these studies indicated that these evaluative differences occurred because avoidance of potential social disruption caused by the necessary accommodating behaviors (i.e., requiring a special arrangement for an individual) was more salient among East Asians than among European Americans. Furthermore, the implied motive underlying such behaviors plays a crucial role in the evaluation process. Standing out by choice (e.g., refusing to eat something because one is a vegetarian) implies willful expression of one's individuality, whereas standing out due to an unavoidable physical condition (e.g., refusing to eat something because one has an allergy) does not. Pursuing an expressive goal by choosing to be different is readily accepted in a European American cultural context, but pursuit of such a goal, at a cost of social disruption, is frowned upon in an East Asian cultural context. Taken together, these findings show that people's willingness to act is by and large propelled by culturally influenced goals.

Choice and Decision Making

Choice and decision making have always been at the heart of cultural psychology (e.g., Iyengar & Lepper, 1999; Kim & Drolet, 2003, 2009; Kim & Markus, 1999; Stephens et al., 2007). The questions that are raised in these studies range from what, why, and how people in different cultures make choices and decisions to how these choices and decisions, in turn, impact their psychology. In this section, we focus our review on how primary cultural goals influence these processes.

Adjustment versus Expression Goals

Relative differences in the importance placed on having choice have been found extensively across national and ethnic cultures (e.g., Iyengar & Lepper, 1999) but cultural differences regarding the importance of choice also exist in other forms of cultures, such as social class and religion. Choice is seen as a form of self-expression among middle-class Americans, so the

freedom to choose is at the center of psychological well-being and satisfaction in this context (Snibbe & Markus, 2005; Stephens et al., 2007). Religion, because it generally invokes beliefs in a supernatural being as an external agent in control, also plays a role in the importance people place on having or exercising choice. Even in cultures in which the pursuit of personal goals is highlighted (e.g., the United States), activating a religious mind-set reduces the need for control and personal choice; for example, when their choice is not honored, European Americans primed with religious concepts tend to yield their desire for primary control and become more accepting and accommodating of others' needs (Sasaki & Kim, 2011). On the other hand, among people from cultures in which adjustment is routinely exercised (e.g., Korea), religion does not significantly impact control and need for choice but rather increases social affiliation (Sasaki & Kim, 2011).

Cultural goals also shape the reasons why people choose to engage in certain actions, even when the actions themselves seem identical on the surface. In cultures in which the goal of self-expression is salient, individuals' actions and decision making, no matter how small and mundane, become forms of self-expression (Kim & Drolet, 2003, 2009; Kim & Sherman, 2007). A strong assumption in these cultures is that one's behaviors correspond with personal preferences, beliefs, and feelings. However, other cultures do not necessarily hold the same assumptions, and social and situational factors are assumed to play a more important role in determining behavior (Morris & Peng, 1994). With regard to this basic assumption about what drives behavior, cultural differences lead to a number of well-known phenomena such as cultural variations in correspondence bias (Choi et al., 1999) and cognitive dissonance (Heine & Lehman, 1997; Hoshino-Browne et al., 2005). More recently, researchers have investigated cultural differences in the degree to which people's beliefs and attitudes influence decision making. As imagined, the link between personally held attitudes and decision making is considerably stronger in individualistic cultures than in collectivistic cultures (see Riemer et al., 2014, for review). Examining the role of individualism and collectivism more directly, in a study analyzing World Value Survey data from 42 nations, Eom, Kim, Sherman, and Ishii (2016) found considerable variation in how strongly individuals' proenvironmental beliefs predict their support for

proenvironmental actions. The researchers found that national-level individualism scores mediated this variation such that the link between beliefs and action is stronger in high individualism cultures compared to low individualism cultures. In more collectivistic cultures, such as Japan, proenvironmental actions are more strongly predicted by perceived norms about engaging in proenvironmental actions rather than personal proenvironmental beliefs (Chan & Lau, 2002; Eom et al., 2016).

Similar variation is also found across social classes. Studies have shown that individuals with higher social class tend to assume that actions are driven predominantly by internal states, personal goals, and emotions, whereas individuals with lower social class tend to place greater emphasis on external social constraints and needs (Kraus et al., 2012; Kraus et al., [Chapter 27](#), this volume). A number of social and psychological explanations proposed by researchers are relevant to cultural goals. Social class shapes the relative importance of personal and shared goals, such that individuals with lower social class pursue more shared and communal goals, whereas those with higher social class pursue more personal goals (Stephens et al., 2007; Snibbe & Markus, 2005). Moreover, compared to individuals with higher social class, those with lower social class are more vigilant with regard to social threats and potential failures (E. Chen & Matthews, 2001; Evans, Shergill, & Averbach, 2010; see Kraus et al., 2012, for review). Consequently, individuals vary, as a function of their social class, in how much they consider social demands versus their own volition when they act or when they make attributions for the actions of others. Researchers have also found a similar type of variation in attribution style across different religious groups. For example, studies indicate that Protestants, for whom the concept of a soul is salient, tend to make more internal attributions compared to Catholics, for whom the concept is not as salient (Li et al., 2012; A. Cohen & Neuberg, [Chapter 32](#), this volume).

In summary, the first part of our review shows that cultural goals underlie a wide range of cultural differences in psychological and behavioral processes at the intrapersonal level. Previously, the primary focus of cultural psychology has been the investigation of cultural influences on these intrapersonal processes. However, the process by which culture shapes a person, whether through parenting, education, or social norms, is inherently social and interpersonal. Therefore, there exists a great need to understand

how interpersonal processes found in different cultures also reflect core cultural goals. The last decade has witnessed active research on the role of culture on interpersonal or relational processes. In the second part of this chapter, we review some of the numerous ways in which social relationships reflect core cultural motives.

CULTURAL MOTIVES AND IMPLICATIONS FOR INTERPERSONAL PROCESSES

The most commonly investigated association between relationships and motivation considers social relationships as the target of human needs. The formation and maintenance of important relationships has been found to be essential to well-being (e.g., Deci & Ryan, 1985; Ryff & Keyes, 1995), and one of the most central human motives (e.g., Baumeister & Leary, 1995; Bowlby, 1969). Belonging is a fundamental and universal human motivation (Baumeister & Leary, 1995). Much like hunger and thirst, the motivation to belong is satiated in similar basic ways across cultures; throughout time and space, similar patterns of bonding—mothers and children, lovers, friends, and groups—have been witnessed. Also like hunger and thirst, failure to satiate the need to belong has major negative consequences (for a review of loneliness, see Cacioppo, Hawkley, & Bernston, 2003).

Despite the universal nature of belongingness and interpersonal connections, however, interpersonal relationships, like individual characteristics and behavioral tendencies, take on many different and culturally shaped forms because the exact patterns of social coordination and interactions needed to ensure mutual survival and thriving depend considerably on the specific local environment in which people live. Much cultural influence is conveyed via social relationships. Good relationships, whether they are with caregivers, peers, or romantic partners, are expected to aid individuals in accomplishing their goals. In the following section of this chapter, we provide a review of how culture-specific goals lead to culturally divergent relationship characteristics. Without challenging the basic premise of social relationships as being at the center of human existence, our review examines cultural differences in how people rely on social relationships to accomplish cultural goals. We center our review on

specific aspects of social relationships: relational mobility, social support processes, and prosocial behavior. We discuss how the aforementioned dimensions of cultural goals (shared vs. personal goals, instrumental vs. emotional goals, adjustment vs. expressive goals, and avoidance vs. approach goals) shape relationship patterns in these three topic areas.

Relational Mobility

This chapter fits in with the recent resurrection of interest in the psychological sciences on the effects of environments on psychological processes and behaviors (see Oishi & Graham, 2010). Perhaps no theoretical construct regarding social relationships has received more attention from this socioecological approach than “relational mobility,” the degree to which opportunities exist within a given context to form, maintain, and terminate social relationships according to personal preferences (Schug et al., 2009; Schug, Yuki, & Maddux, 2010; Yuki et al., 2007). Cultures low in relational mobility are characterized by “sticky” long-term and duty-bound relationships, whereas cultures high in relational mobility favor fluid and transient relationships that are easily made and unmade.

Recent years have seen tremendous efforts in documenting regional differences in levels of relational mobility. Typically, East Asian and West African countries measure low in mobility, whereas North America scores high (Adams, 2005; Falk, Heine, Yuki & Takemura, 2009; Schug et al., 2009; Wang & Leung, 2010; Yuki & Schug, 2012; Yuki et al., 2015). Although somewhat weak, a positive association has been found between individualism and relational mobility scores, where individualistic cultures show a tendency to be more socially mobile (Yuki et al., 2015). Within national borders, researchers have found that urban regions are typically characterized by higher relational mobility compared to rural areas (Yamagishi, Hashimoto, Li, & Schug, 2012), and wealthier communities are more socially mobile than low socioeconomic status (SES) communities (Snibbe & Markus, 2005).

Relational mobility offers a useful explanatory mechanism for many previously established behavioral differences across cultures. Although this body of research typically examines relational mobility as a causal factor

driving social behaviors, different patterns of relational mobility presumably emerge as adaptive responses to ecological and environmental constraints. Therefore, we see patterns of high and low relational mobility as cultural adaptations to environments that necessitate different types of relationship goals.

Instrumental versus Emotional Goals

In an environment that requires individuals to work together in order to survive, a pattern of low relational mobility, which locks individuals into a web of interdependence, would ensure personal and collective success in achieving environmentally motivated goals over the long haul and increase the chances of collective survival. In contrast, high relational mobility is an adaptation to environments in which the instrumental function of relationships is diminished, and expressive and emotional goals are prioritized. When emotional goals are paramount, individuals reap the most benefit from being able to float effortlessly between relationships that make them feel good or terminate relationships that no longer provide these services.

Consistent with this proposition, behavioral outcomes of high relational mobility tend to foster positive emotional aspects of social interactions, whereas behavioral outcomes of low relational mobility tend to foster instrumental aspects of social relationships. In one of the earliest studies on the topic, for example, Schug et al. (2010) proposed that relational mobility may explain why East Asians disclose less personal information to others compared to Westerners. Treating relational mobility as a mediator of the East–West cultural difference, they showed that environments high in relational mobility create incentives for individuals to self-disclose in order to build and strengthen their social ties. Similarly Wang, Leung, See, and Gao (2011) argued that relational mobility is the mechanism behind cultural differences in patterns of rewarding honesty and punishing deception, such that Americans reward honest individuals more than they punish deceptive persons, whereas East Asians reward and punish equally (Wang & Leung, 2010). In high mobility cultures, rewarding behaviors serve a positive and much-needed relationship-promoting function (akin to self-disclosure).

Punishment to prevent undesirable behaviors, on the other hand, is not considered worthy of effort in environments in which it is easier to discard a relationship.

Relational mobility has also been found to mediate cross-cultural differences in a range of affect- and emotion-related processes. High relational mobility tends to increase positively valenced and approach-oriented experiences such as self-enhancement (Falk et al., 2009), preferences for homophily (Schug et al., 2009), general trust (Yuki & Schug, 2012), happiness (Yuki, Sato, Takemura, & Oishi, 2013), self-esteem (Sato & Yuki, 2014), and the desire to be unique (Takemura, 2014). In contrast, low relational mobility tends to increase negatively valenced and avoidance-oriented experiences such as shame (Sznycer et al., 2012) and sensitivity to social rejection (Sato, Yuki, & Norasakkunkit, 2014).

Rather than promoting mutually positive experiences, primary goals in low relational mobility cultures are instrumental ones, especially to promote self-improvement. In order to improve on something, an individual must first be aware of his or her shortcomings. Relational partners can provide one of the best sources of honest information about one's personal deficiencies; however, this type of information can be shared only if there is no fear of relationship dissolution. Imada, Rodriguez Mosquera, and Ishii (2015) examined how participants in Japan (a culture with low relational mobility) and the United Kingdom (a culture with high relational mobility) rated friendship partners who provided evaluations that were equal to, better than, or worse than their self-evaluations. The U.K. participants felt good about their relationships when friends' evaluations either matched or exceeded their self-evaluations. For Japanese participants, however, friendship quality dropped when the friend's evaluation was above their own. Because self-improvement is a primary goal in Japan, participants felt best about relationship partners who told them the truth, even when the information was negative. This type of truth telling, of course, is only made possible in contexts where relationships are sticky. Similarly, other research looking at physiological responses has found an association between criticism from family and friends and increased inflammatory activity among European Americans but not among Asian Americans or Hispanic Americans (Chiang, Saphire-Bernstein, Kim, Sherman, & Taylor, 2013; Fuligini, Telzer, Bower, Cole, Kiang, & Irwin, 2009).

Social Support

A tremendous amount of research shows the benefits of both perceived and received support from close others during stressful times (e.g., Collins, Dunkel-Schetter, Lobel, & Scrimshaw, 1993; Morling, Kitayama, Miyamoto, 2003). People universally rely on each other, and this is especially true during times of heightened stress. “Social support” has been defined as the perception or experience that one is loved and cared for and part of a network of mutual commitment (Cobb, 1976; S. Cohen & Wills, 1985; Wills, 1991). Social support is also considered to be one of the most effective means of coping with difficult situations (Seeman, 1996; Taylor et al., 2004).

A decade of research has confirmed that social support occurs in culturally appropriate and culturally inappropriate forms. Among East Asians and North Americans, who comprise the bulk of studied samples, significant cultural differences have been found in how social support is sought, given, received, experienced, and evaluated (e.g., Kim et al., 2006; Mojaverian & Kim, 2013; Taylor et al., 2004; Uchida, Kitayama, Mesquita, Reyes, & Morling, 2008). In large part, these differences in social support interactions stem from divergent relationship goals across cultures.

Shared versus Personal Goals

The primary function of social support differs between more collectivistic and more individualistic cultures. Studies investigating both support seeking (e.g., Ishii, Mojaverian, Masuno, & Kim, 2017) and support provision (e.g., J. Chen et al., 2012) demonstrate that in more collectivistic cultures, the primary function of social support is to enhance and affirm social bonds, whereas in more individualistic cultures, the primary function of social support is to enhance the recipient’s self-esteem. It is important to note that although the motive to prioritize a shared goal is prevalent among those from more collectivistic cultures, how this motive is manifested in specific support transactions varies considerably across collectivistic cultures. Latinos with *convivial collectivism* tend to maintain good relationships by reducing the expression of conflict and emphasizing the expression of warmth and affirming relationship bonds, whereas East Asians with

harmony collectivism tend to be cautious in support seeking in order to maintain social harmony (Campos & Kim, 2017). Moreover, recent studies show that collectivism may interact with relationship norms in shaping social support use. In India (collectivistic with communal norms), social support is more readily used, but in Japan (collectivistic with exchange norms), social support is less readily used, compared to the United States (individualistic with exchange norms), where the tendency falls in between (Miller, Akiyama, & Kapadia, 2017). It appears that the motive for shared goals, common in collectivistic cultures, amplifies the influence of communal and exchange norms in social support transactions.

Adjustment versus Expression Goals

The earliest studies to investigate culture and social support focused primarily on how social support is sought during stressful events (Taylor et al., 2004; Kim et al., 2006). Compared to European Americans, Asians and Asian Americans were significantly less likely to report drawing on social support to cope with difficult situations. Furthermore, Asians and Asian Americans expected support seeking to be less effective, especially in close relationships. Key to explaining this difference is the element of self-disclosure sometimes involved in support seeking. In cultural contexts in which prioritized goals include expressing oneself, the strategies of disclosing one's needs and feelings make sense. Indeed, Taylor, Welch, Kim, and Sherman (2007) found that explicit social support seeking, involving disclosure and explicit solicitation of support, is most effective for European Americans. In contrast, explicit support seeking is harmful to the psychological and biological well-being of Asians and Asian Americans, who prioritize adjustment goals because they are concerned that such support seeking burdens their close others or harms others' evaluation of them. Explicit support seeking, in a laboratory setting, for example, increased production of the stress hormone cortisol in Asian and Asian American participants (Taylor et al., 2007).

Avoidance versus Approach Goals

One of the documented reasons for the cultural difference in the likelihood and effects of support seeking is that Asians and Asian Americans worry about the potentially negative consequences of support seeking, such as interference with relationship harmony and the risk of losing face (Taylor et al., 2004). Active and explicit forms of support seeking cause distress in interdependent cultures because individuals are more concerned with avoidance goals over approach goals. This is not to say that Asians and Asian Americans do not benefit from social support. In fact, research shows that perceived social support receipt has more benefits for collectivistic than for individualistic people (e.g., Campos, Schetter, Abdou, Hobel, Glynn, & Sandman, 2008; Uchida et al., 2008). The difference is that Asians and Asian Americans seem to benefit more from implicit forms of support seeking, which do not require making overt and disruptive disclosures and demands. Examples of such implicit forms of support seeking involve spending time with close others, without discussing one's problem or reminding oneself of close others. This type of support use is more likely to reinforce belongingness, without worry about potential costs.

Directly testing this idea, Mojaverian and Kim (2013) found that support receipt is more effective for Asians and Asian Americans when they do not have to ask for it directly. In one study, participants worked on a set of math problems in the same room with a confederate, who was described as a math major who could potentially help with difficult problems if needed. In a solicited support condition, the confederate gave assistance only if requested directly by the participant, whereas in the unsolicited condition, the confederate offered help before the participant had a chance to ask. Asian American participants who received unsolicited support fared significantly better than Asian American participants who had to solicit support. These individuals reported higher levels of self-esteem and lower levels of stress after receiving the unsolicited support; however, the opposite pattern was observed among European American participants. Clearly, social support is a universally valuable resource, but prioritized cultural goals shape the form of support that is most helpful.

Instrumental versus Emotional Goals

Another distinction that has emerged as an important cross-cultural difference is the divergent preference for emotional versus problem-focused support. Compassion, encouragement, and reassurance may be subsumed under the rubric of emotional support. The primary objectives of this type of support provision are to reaffirm the individual, soothe negative feelings, and boost self-esteem. Not surprisingly, this type of support provision is preferred in independent cultures that prioritize emotional goals (J. Chen et al., 2012). Research conducted with North American samples indicates that emotion-focused support provision is typically the most beneficial type of support (e.g., Maisel & Gable, 2009). This same type of support provision is less common in collectivistic cultures. Instead, problem-focused support is more frequently used in these cultures. Problem-focused support, such as giving advice, or providing tangible resources, such as money or shelter, is better suited to contexts that prioritize instrumental goals; therefore, it is more common in collectivistic cultures (J. Chen et al., 2012; Chentsova-Dutton & Vaughn, 2012). Research conducted in the United States and Japan also indicates that Americans' support provision is motivated by the goal of increasing recipients' self-esteem, as well as relationship closeness, whereas Japanese support provision is solely motivated by increasing closeness (J. Chen et al., 2012). Interestingly, this analysis suggests that relationship closeness, which was a central motivation of support provision in both cultures, is achieved in culturally divergent ways. Instrumental support provision achieves this goal in Japan, and more emotional support provision achieves the same goal in the United States. Similarly, research comparing advice giving in collectivistic Russia and individualistic America indicated that Russians are much more likely to provide both solicited and unsolicited advice, which is an important form of practical, problem-focused support in a Russian cultural context that fosters practical interdependence (Chentsova-Dutton & Vaughn, 2012).

In summary, social support is an effective means of coping with stress in both independent and interdependent cultures; however, the precise forms that social support interactions take are shaped by the cultural goals that individuals prioritize in their relationships. As indicated, patterns of relational mobility and patterns of social support diverge between cultures with different goal orientations. In the next section, we review cultural differences in patterns of prosociality.

Prosocial Behavior

Prosocial behavior is a comprehensive term referring to a variety of activities, including altruism, helping, volunteering, and cooperation, that are advantageous to other persons or society in general (Pillavin, Dovidio, Gaertner, & Clark, 1982). Most research suggests that humans are universally inclined toward prosocial behaviors (e.g., Batson & Shaw, 1991; MacDonald, 1984). Evolutionary theories see prosociality as an adaptive strategy in environments characterized by recurring interpersonal interactions (e.g., S. Preston & de Waal, 2002; Trivers, 1971). In spite of what appears to be a universal inclination toward prosociality, however, studies also point to significant cultural variation in how much, when, and how individuals choose to help others, and many of these cultural differences may be explained by cultural goals.

Shared versus Personal Goals

Although the pattern of findings is complex, one consistent finding is that cultures shape the gist of how and why people help each other. First, studies indicate that there are cultural differences in how much people view helping others as an obligation. In a study investigating the meaning of power across different cultures, Torelli and Shavitt (2010) found that cultures high in horizontal collectivism, such as those of Northern Europe and Latin America, which value interdependence but devalue social hierarchy, embrace socialized power beliefs; that is, they consider power as a means to achieve shared goals such as helping others and taking care of those who are powerless. Conversely, cultures high in vertical individualism, such as the United States, which place great importance on hierarchies of success, view power as a means to achieve personal goals such as advancing self-interest and distinguishing oneself.

Of course, this does not mean that prosocial actions occur less in more individualistic societies. Rather, studies show that culture influences why people engage in prosocial actions. Generally speaking, prosociality is driven by in-group, concrete, and duty-bound concerns in interdependent cultures and by generalized and abstract justice concerns and free-choice in

individualistic cultures (Berman, Murphy-Berman, & Singh, 1985; Kashima, Siegal, Tanaka, & Isaka, 1988; Miller & Bersoff, 1992; Miller, Bersoff, & Harwood, 1990; Miller, Wice, & Goyal, [Chapter 16](#), this volume); that is, the decision to help others is motivated by interpersonal duties and obligations to fulfill shared goals within one's ingroup in collectivistic cultures and by the need to fulfill one's internal principles and moral concerns in individualistic cultures (for a related discussion, see Eom et al., 2016).

This difference helps explain some of the seemingly paradoxical phenomena of impersonal prosociality such as volunteering and charitable giving. Unlike helping close friends or family, volunteering typically takes place in a formal organizational context and is a more planned, impersonal, and nonobligatory form of helping (Penner, Dovidio, Piliavin, & Schroeder, 2005). Simon, Stürmer, and Steffens (2000) found that volunteering to help an outgroup is positively associated with viewing oneself as an individualist and is negatively associated with viewing oneself as a collectivist. Similarly, in a meta-analysis of studies conducted in 42 different countries, Allik and Realo (2004) found that social capital, which involves volunteering, increases with individualism.

Beyond the variation in how much people engage in these impersonal prosocial actions, individualism seems to influence the reasons for engaging in these behaviors. More specifically, individualism particularly increases prosocial behaviors that promote others' pursuit of personal goals. For example, an analysis of regional variations in the United States shows that state-level individualism predicts volunteering and donations to organizations that promote individualistic values (e.g., self-development and self-expression), such as those geared around the arts, workplace, and education; however, individualism does not predict volunteering or donating to organizations that promote health and human services (more instrumental causes) or religious charities (Kimmelmeier, Jambor, & Letner, 2006); that is, although both types of activities are intended to promote the well-being of society in general, people from more individualistic contexts tend to choose to engage in prosocial activities that aid others in achieving their personal goals, including self-actualization and personal growth, in particular.

Religious cultures also accentuate the importance of shared goals over personal goals. A quickly growing body of research reveals that goals

emphasized by religious cultures have substantial implications for how much and whom people choose to help. Religious concepts, such as the concept of God, when primed or personally endorsed, increase a variety of prosocial behaviors and cognitions such as fair decision making in a dictator game (Norenzayan & Shariff, 2008; Shariff & Norenzayan, 2007), prosocial intentions (Pichon, Boccato, & Saroglou, 2007), and cooperative behaviors (Rand et al., 2014). Xygalatas (2013) also found that merely being in a religious environment, or in view of religious symbols, activates more cooperative behavior. In a recent metaanalysis of more than 90 studies, Shariff, Willard, Andersen, and Norenzayan (2016) found robust effects for the positive impact of religion on prosociality.

However, it is important to note that research often reveals that these tendencies are parochial in nature. In fact, numerous studies show that religion sometimes increases prejudice and outgroup derogation (e.g., Demoulin, Saroglou, & Van Pachterbeke, 2008; Hall, Matz, Wood, 2010; Johnson, Rowatt, & LaBouff, 2010; McKay, Efferson, Whitehouse, & Fehr, 2011; Whitley, 2009; see A. Cohen & Neuberg, [Chapter 32](#), this volume). Given that nearly all religions demand adherence to moral codes that encourage the kind treatment of others, these results appear paradoxical. A set of studies that tackled this paradox (J. Preston & Ritter, 2013) found differential effects of activating the concept of God as a personal belief and the concept of religion as a group affiliation. Activating the concept of God increased more generalized prosociality, but activating the concept of religion increased parochial prosociality. Taken together, these findings suggest that religion has both individual and collective elements, and we argue that the relative importance of these different elements underlies different prioritization of personal versus shared goals. Highlighting God increases principle-based generalized prosociality, a form of prosociality that is common in independent cultures. However, highlighting religious group membership increases prosociality bounded by group membership, a form of prosociality that is common in interdependent cultures (Graham & Haidt, 2010; J. Preston, Ritter, & Hernandez, 2010; Saroglou, 2002).

Adjustment versus Expression Goals

Threat is thought to be a trigger for attachment behaviors (e.g., Bowlby, 1969); similarly, under threatening circumstances, interdependence emerges as a strategy for survival; that is, building relationships is a way to deal with threatening circumstances, and ingroup prosociality can be seen as the glue that holds together networks of interreliance. Thus, working-class individuals, who presumably experience more chronic threat, have been shown to exhibit comparatively more prosocial behaviors than do middle-class individuals, and these behaviors are especially directed toward the ingroup.

When one's personal fate is intertwined with that of others, individuals master skills that attune them to the thoughts, feelings, and actions of others, and they adjust their own thoughts and behaviors to be aligned with relevant others. Indeed, research has documented that working-class individuals demonstrate greater empathic accuracy than their upper-class counterparts. In a series of studies, Kraus, Côté, and Keltner (2010) found that lower SES individuals, or individuals who were induced to feel lower in status, performed better on a variety of empathy tasks. Participants who rated themselves as having lower SES were also better able to judge the emotions of their partner in a mock job interview. Page-Gould, Koslov, and Mendes (2010) demonstrated that lower class individuals even experience parallel physiological responses when interacting with others. For example, when playing the board game Taboo, participants from families with lower income and education levels demonstrated cardiac contractility, a measure of sympathetic nervous system activation, following the same response in their gaming partner. However, no such physiological contagion was observed among participants who reported higher levels of income and education.

Religion, with its many norms and proscriptions, also fosters an emphasis on adjustment over expression goals. Saroglou, Corneille, and Van Cappellen (2009), for example, found that subliminal religious primes can make participants more submissive and likely to be susceptible to the demands of an experimenter, even when these demands require a problematic action such as enacting revenge against another participant. In one study, although priming of religious concepts alone increased prosocial behaviors, when the prime was coupled with a request from the experimenter to take revenge on another participant who had been rude,

religious priming actually led to more negative behavior. These findings help explain why previous researchers have found that religious primes facilitate both more prosocial (e.g., cooperative) and more antisocial (e.g., prejudiced) behaviors. Religious priming especially fosters prosociality when prosocial actions support harmony, group cohesion, and shared goals, as well as adjusting one's behaviors to social expectations and demands.

In summary, the second part of our review reveals that cultural goals shape how people engage in social interactions and relationships, which in turn foster and reinforce behaviors consistent with culturally central goals. Considering cultural goals in interpersonal processes allows us to place culturally diverse relationship patterns in a larger and more coherent framework.

CONCLUSION

In this review we have systematically analyzed the existing literature on cultural differences in psychological processes and behaviors to demonstrate how culturally prioritized goals shape both intrapersonal and interpersonal behaviors. In particular, we have focused on the underlying reasons behind various motivational processes such as behaving in one way over another, increasing or decreasing certain behaviors, and maintaining or changing behaviors. The review has also highlighted some of the ways in which knowledge about cultural goals may be used to promote desirable outcomes such as positive health behaviors and increased academic motivations.

There are two insights from this review that we would like to underscore. First, we want to stress that across different cultural regions and forms of culture, a full understanding of human behaviors must begin with a consideration of the particular demands posed by ecological, historical, and social environments and the implication that these environmental factors have for culturally prioritized goals. Second, we want to emphasize that the investigation of cultural influences requires contextualizing individuals in their relationships, which are the primary conveyers of cultural patterns of psychology and behavior. In other words, this chapter affirms the wisdom found in seeing a person within a complex web of relational, structural, historical, and ecological influences, which we call culture.

NOTE

1. The influence of religion has been investigated by either comparing patterns of psychology and behaviors associated with particular religious groups (e.g., Protestants vs. Catholics) or examining the role of religion in general by comparing the religious and the nonreligious, regardless of the content of particular religions. In this chapter, we primarily discuss research using the latter approach because of the focus on social functions of religion shared across all religions. For a more detailed review of religion, see A. Cohen and Neuberg ([Chapter 32](#), this volume).

CHAPTER 11

Cultural Influences on Emotion

Established Patterns and Emerging Trends

Jeanne L. Tsai and Magali Clobert

Over the last decade, significant empirical research has examined the influence of culture on a variety of emotional and affective processes. In this chapter, we review three established empirical patterns of differences in emotion between Western and East Asian cultures that stem from independent versus interdependent models of self. These patterns concern (1) the focus of emotion, (2) the value placed on emotional expression versus suppression, and (3) the value placed on experiencing positive (vs. negative) affective states, and on high- versus low-arousal positive states. This work reveals that many assumptions that stem from Western views of emotion are less applicable to East Asian contexts. We then discuss the importance of considering cultural differences in emotion for health, business, and other applied settings. We end with a description of some emerging trends in the culture and emotion literature that broaden existing research by including different independent and interdependent contexts; examining interactions with age, gender, and social class; studying acculturative processes; comparing different religions; exploring other cultural factors; and using neuroimaging and genetic methods. Together, these research efforts reveal the myriad ways in which culture shapes emotional life.

Emotions and other affective states play a critical role in our daily lives. They allow us to respond to environmental events rapidly and in a coordinated way. They help us make decisions about what to do and how to act. They can

drive our actions and preferences. They tell us about the intentions of others and make it easier for us to predict their actions. For these reasons, many scholars have long believed that emotions are hardwired and universal. At the same time, scholars (as early as Darwin, 1872/1998) have also noted the considerable “diversity” of emotional expression, which has led them to wonder about the degree to which emotions and other affective states are socially transmitted and culturally variable. Although empirical research, including our own, has demonstrated considerable cultural similarities in emotional experience and expression (e.g., Breugelmans et al. 2005; Scherer, 1997; Tsai, Chentsova-Dutton, Friere-Bebau, & Przymus, 2002; Tsai & Levenson, 1997; Tsai, Levenson, & Carstensen, 2000), a significant body of research within the last decade has also demonstrated considerable cultural differences. We focus on these differences in this chapter.

This chapter is divided into four main sections. In the first section, we provide a brief description of the origins of Western models of emotion, which dominate current research in affective science. In the second section, we describe three consistent empirical patterns of cultural differences in emotion that have emerged in the last decade, what we refer to as “established” cultural patterns. These patterns suggest that the dominant model of emotion in many East Asian contexts differs from the dominant model of emotion in many Western contexts. In the third section, we discuss the practical implications of these cultural differences. Finally, in the fourth section, we discuss emerging trends in the field that promise to reveal new insights about culture and emotion in the decades to come. But first, we define our terms.

DEFINITIONS

By “culture,” we refer to shared and historically derived ideas that are instantiated and transmitted through practices, artifacts, and institutions (Kroeber & Kluckhohn, 1952; Markus & Conner, 2013). People create these ideas, and these ideas in turn shape how people think, feel, and behave, a process that Markus and Conner (2013; Markus & Hamedani, [Chapter 1](#), this volume) refer to as the “culture cycle.” Among the many functions of culture, one is to teach people what is moral, virtuous, good, and right, as

well as what is immoral, sinful, bad, and wrong (Shweder, 2003; Miller, Wice, & Goyal, [Chapter 16](#), this volume). Because most cross-cultural research on emotion has focused on comparisons between Western and East Asian cultures, we focus on these contexts in this chapter, although we discuss other cultural differences in the final section. Initially, research compared Western and East Asian cultures because ethnographic accounts and personal observation suggested that they differed emotionally (e.g., Benedict, 1946; Hsu, 1953/1981; Kleinman, 1988; Potter, 1988; Wierzbicka, 1994); however, as we describe below, research later focused on these comparisons for theoretical reasons as well (Markus & Kitayama, 1991).

In the literature, researchers use the terms “emotion,” “affect,” and “feeling” to refer to a broad range of phenomena that involve changes in subjective experience, neural and physiological response, and behavior at varying intervals of time (seconds, minutes, days). “Emotional responses,” such as anger, fear, and disgust, typically refer to short-lived, highly arousing states that occur in response to a meaningful event (Ekman, 1994). “Affect” refers to feelings that can be described in terms of valence (positive or negative) and arousal (high or low) (Feldman Barrett & Russell, 1999; Larsen & Diener, 1992; Watson & Tellegen, 1985; Thayer, 1989; as illustrated in [Figure 11.1](#)).

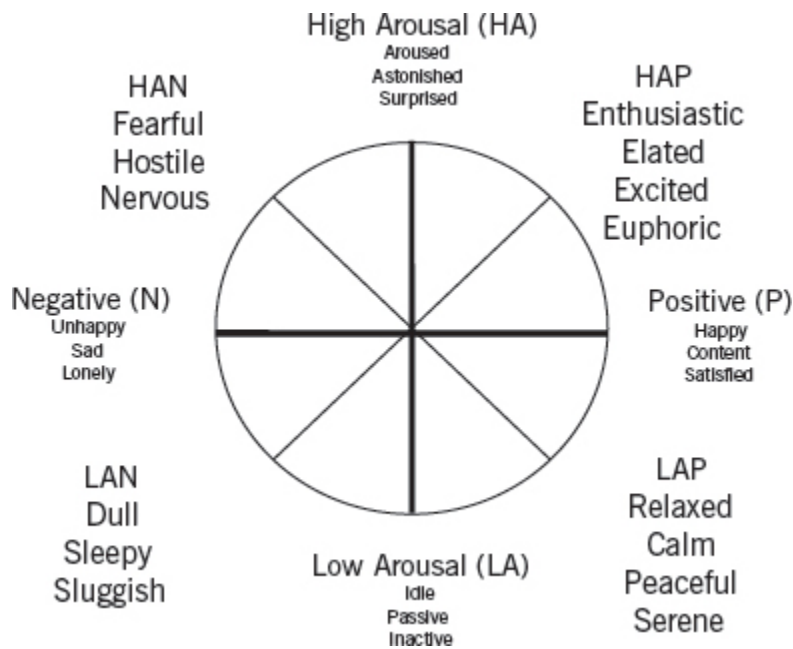

FIGURE 11.1. Two-dimensional model of affect. HAP, high arousal positive states; LAP, low arousal positive states; HAN, high arousal negative states; LAN, low arousal negative states.

For instance, excitement and enthusiasm are “high-arousal positive states”; calm and relaxation are “low-arousal positive states”; fear and nervousness are “high-arousal negative states”; and dullness and sluggishness are “low-arousal negative states.” Both emotion and affect may occur for a few seconds (“states”), may last a few days (“moods”), or may be general tendencies to feel a certain way (“traits”) (Davidson, 1994; Watson & Clark, 1994). Cross-cultural studies have focused on all of these different phenomena.

WESTERN MODELS OF EMOTION

Dominant models of emotion in the psychological literature are based on the theories of three primary 19th- and 20th-century Western thinkers: Charles Darwin, William James, and Sigmund Freud. Darwin (1872/1998) first proposed an evolutionary view of emotion by observing connections between “man” and “animals” in his book *The Expression of Emotion in Man and Animals*. He believed that in order to survive, organisms had reflex-like responses that allowed them to respond to environmental threats and

rewards instantaneously and automatically, and that emotional expressions were residues of these responses (Oatley, Keltner, & Jenkins, 2006). Later, William James (1890) proposed that the bodily changes that occurred in response to a meaningful event were the core part of an emotional response. He also proposed a cathartic-hydraulic view of emotion, in which verbal, facial, and physiological responses were different channels for releasing emotional energy elicited by a stimulus. If one channel were blocked (e.g., people could not express their emotions verbally), emotional energy would be released more intensely through other channels (e.g., physiologically). This theorizing was consistent with Sigmund Freud's view of the psyche as a fluid flowing through a system (Freud, 1921/1946). While Freud never used the term "hydraulic model" himself, he viewed emotions as placing pressure and tension on a system that would explode if those emotions were not expressed. Moreover, Freud saw emotions as the basis of different forms of psychopathology (Oatley et al., 2006). James was also interested in the links between emotion and "healthy mindedness" (James, 1902). He believed that people create their own happiness by believing in the meaning of life—even if the belief is not rational—and that depression, anxiety, and other forms of distress resulted from having pessimistic beliefs (James, 1907, 2000).

Although there have been many other emotion theorists since Darwin, James, and Freud, the views of these three scholars have provided the foundation for many core assumptions about emotion that dominate the Western empirical literature. From this perspective, emotions at their core are intrapsychic experiences that are expressed through multiple channels of response. If one of those channels is suppressed or blocked, the emotional response is diverted to another channel. Moreover, according to this model, frequent emotional suppression places too much pressure on the system, resulting in poor mental and physical health. This is particularly true for aggressive impulses and other negative emotions, which could result in severe psychopathology if not expressed in socially acceptable ways. As shown below, these theories, while products of individual thought, also reflect the cultures in which Darwin, James, and Freud lived.

While empirical research on emotion started in the early 1900s, cross-cultural research on emotion did not begin until the 1960s and 1970s. Most of this research predicted that while there might be cultural differences in the triggers and displays of emotion, there would be no differences in the

core aspects of emotional response. For instance, in Ekman's neurocultural model of emotion, he proposed that the triggers of emotion, the display rules regarding emotional expression, and even the consequences of emotional expression, were culturally variable. The one exception was the "facial affect program," or the facial expressions associated with specific emotional states, which he proposed was a core aspect of emotional response and therefore universal (Ekman, 1972). To test this model, Ekman and his colleagues presented individuals of different nations photos of facial expressions that represented different specific emotional states. Across the different nations sampled, individuals were able to recognize the emotions depicted in the photos at above chance levels (Ekman et al., 1987), leading Ekman and others to conclude that emotions could be recognized across cultures. Thus, many researchers concluded that the Western model was a universal model of emotion.

CULTURAL DIFFERENCES IN EMOTION: ESTABLISHED EMPIRICAL PATTERNS

Although some scholars continued to conduct cross-cultural studies of emotion in the 1970s and 1980s, a significant resurgence of interest in culture and emotion began in the 1990s, after Hazel Markus and Shinobu Kitayama (1991) proposed that national differences in individualism–collectivism (Hofstede, 1980; Triandis, 1989) produced different models of the self. In particular, Markus and Kitayama (1991) focused on Western and East Asian contexts, and described how these contexts promoted "independent" and "interdependent" models of self, respectively. In "independent" models of self, individuals are viewed as being distinct from others; defined in terms of their beliefs, desires, and preferences; taught to prioritize their own needs over those of others; and encouraged to influence others (i.e., change their environments to be consistent with their own beliefs, desires, and preferences). In contrast, in "interdependent" models of self, individuals are viewed as being connected to others; defined in terms of their duties and relationships with others; taught to prioritize others' needs over their own; and encouraged to adjust to others (i.e., change their beliefs, desires, and preferences to be consistent with their environments). Markus

and Kitayama proposed that these different models of self would shape emotion (as well as cognition and motivation) in specific ways. In the next section, we describe three empirical patterns based primarily on research conducted within the last decade that test the ideas laid out by Markus and Kitayama. These patterns are graphically represented in [Figure 11.2](#).

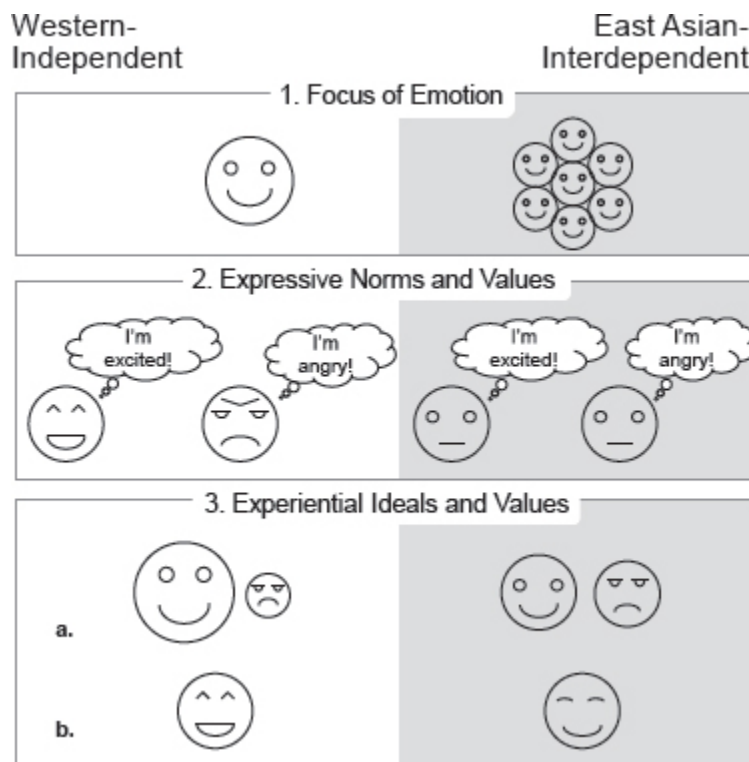

FIGURE 11.2. Three empirical patterns of differences in emotion between Western (independent) and East Asian (interdependent) cultures.

Pattern 1: Emotions Are More Interpersonally Focused in East Asian Than Western Contexts

Because cultures with independent models of self value personal achievement, autonomy, and distinctiveness, emotions in these cultures should focus on the personal self and emphasize distinctiveness. Conversely, because cultures with interdependent models of self value group achievement, interpersonal connectedness, and fitting in with others, emotions in these cultures should focus on others and emphasize

connection with others. In other words, members of Western cultures should experience emotions that distinguish themselves from others more, whereas members of East Asian cultures should experience emotions that connect themselves with others more. Furthermore, emotions should be most intense for Westerners when they think about their uniqueness, whereas emotions should be more intense for East Asians when they think about their connections with close others.

Consistent with these hypotheses, several studies have demonstrated that Japanese report experiencing socially engaging emotions (e.g., feeling connected, friendly, guilty, ashamed) more frequently and intensely, and experiencing socially disengaging emotions (e.g., feeling superior to, proud, angry, and frustrated) less frequently and intensely than members of many different Western countries (i.e., Germany, the United Kingdom, and the United States) (Kitayama, Mesquita, & Karasawa, 2006; Kitayama, Park, Sevincer, Karasawa, & Uskul, 2009). These cultural differences have been replicated among children, suggesting that they emerge relatively early in life (Furukawa, Tangney, & Higashibara, 2012). These differences are directly related to the types of situations that individuals encounter: situations eliciting anger occur more frequently in U.S. American than in Japanese contexts, whereas situations eliciting shame occur more frequently in Japanese than in U.S. American contexts (Boiger, Mesquita, Uchida, & Barrett, 2013b).

Similarly, and consistent with the above hypotheses, emotional experiences seem to be more self-focused and less other-focused in independent than interdependent contexts. For instance, Chentsova-Dutton and Tsai (2010) primed individuals to think about themselves or their family members by listing three events that involved themselves or their family members. Participants then watched emotional film clips. Asian Americans reported and expressed more intense emotions during the film clips when they had focused on family members versus themselves prior to watching the clips. In contrast, European Americans reported and expressed more intense emotions during the film clips when they had focused on themselves versus family members prior to watching the clip. Similarly, in Uchida, Townsend, Markus, and Bergsieker (2009), Japanese athletes used more emotion words than did U.S. athletes when asked about their relationships; Japanese participants implicated others more often than did U.S. American

participants when describing athletes' emotional reactions to winning; Japanese participants inferred more emotions than European Americans did when athletes mentioned relationships in their self-descriptions; and Japanese inferred more emotions for athletes pictured with teammates, whereas European American participants inferred more emotions for athletes pictured alone. Thus, emotions appear to focus on others more in Japanese versus U.S. contexts.

These different foci are also reflected in people's perceptions of others' emotions (for a review, see Barrett, Mesquita, & Gendron, 2011). Several studies show that European Americans rely primarily on the information displayed by a central target when identifying how that central target feels, while East Asians tend to also rely on information provided by the other people in the target's environment (e.g., Masuda et al., 2008). For instance, Masuda and colleagues showed European American and Japanese participants cartoons depicting a central target displaying a happy, sad, angry, or neutral face. The central target was surrounded by four other people, who displayed either the same or different emotional facial expressions as the central target. Participants were then asked to rate the degree of joy, sadness, and anger displayed by the central target. As predicted, Japanese participants' judgments of the central target's emotion were more influenced by the expressions of other people surrounding the central target than were European American participants' judgments of the central target's emotion (Masuda et al., 2008). Moreover, Japanese ratings of the central targets' emotional intensity increased when that target's emotions were consistent with the expressions of the other people surrounding him or her. In contrast, European American ratings of the target's emotional intensity did not vary as a function of the other people's expressions.

In a follow-up study, Masuda and colleagues (2008) used eye-tracking to demonstrate that Japanese attended to the other people surrounding the central figure more than did Westerners when judging the central target's emotional expression. These findings hold when real faces are used, when the size of the target is the same as the size of the target's conspecifics, and when the amount of observation time was controlled (Masuda, Wang, Ishii, & Ito, 2012). Similarly, Goto, Yee, Lowenberg, and Lewis (2013) compared Asian American and European American participants' N400 responses, which are sensitive to semantic matches and mismatches between figures

and background images, to facial expressions that were paired with either congruent or incongruent background affective pictures (e.g., a happy face with a positive or negative scene). As expected, Asian Americans showed greater N400 responses to incongruent versus congruent picture–face pairs than did European Americans, suggesting that Asian Americans were more sensitive to the background pictures than were European Americans when they viewed the central target’s emotional face.

Interestingly, compared to European Americans, East Asian participants seem to be particularly attuned to surrounding faces. In Ito, Masuda, and Li (2013), European Canadian and East Asian participants were asked to rate the intensity of a central target’s emotional expression surrounded by either affectively salient landscape scenes or by other people’s emotional expressions. Both European Canadians and East Asians reported higher intensity of the central target’s emotion when the landscape scenes were affectively congruent versus incongruent (e.g., smiling target paired with a beautiful beach vs. a decrepit old building). However, while East Asians’ ratings of the central target’s emotion were also influenced by the emotional expressions of other people, European Canadians’ ratings were not.

In summary, as predicted by independent and interdependent models of self, considerable research now demonstrates that emotions in Western contexts are focused more on the individual separate from others (intrapersonal), whereas emotions in East Asian contexts are focused more on individuals in the context of others (interpersonal) (top panel of [Figure 11.2](#)).

Pattern 2: East Asian Contexts Value Emotional Expression Less and Suppression More Than Western Contexts

A second pattern that has received considerable attention in the empirical literature concerns the display of emotion; indeed, much of the first work on culture and emotion focused on cultural differences in “display rules,” or attitudes about what is appropriate to show on one’s face in a given situation (Matsumoto, 1990, 1993). In Western independent cultural contexts, openly and freely expressing one’s emotions is strongly encouraged because it

reinforces the self as separate and unique. As a result, emotional control and suppression in Western contexts are associated with experiential avoidance (Su, Wei, & Tsai, 2014; Wei, Su, Carrera, Lin, & Yi, 2013) or the unwillingness to accept and experience distressing thoughts or other internal events (Hayes, Strosahl, & Wilson, 1999). This construct reflects cathartic and hydraulic models of emotion, in which emotional expression is critical to psychological health. In interdependent cultural contexts, however, the open expression of emotions may hurt interpersonal harmony by making others feel bad (see Butler, Lee, & Gross, 2009; Soto, Levenson, & Ebling, 2005; Su et al., 2014; Wei et al., 2013). Consequently, East Asian cultural contexts value emotional expression less and suppression more than do Western cultural contexts (Ford & Mauss, 2015; Matsumoto, 1990; Su et al., 2014; Wei et al., 2013).

This cultural difference in the value placed on emotional expression versus suppression suggests that the consequences of emotional expression and suppression might differ in Western and East Asian contexts. For instance, studies have demonstrated that suppressing the facial expression of an emotion increases physiological arousal, as suggested by cathartic-hydraulic models (Gross & Levenson, 1993, 1997). But is this true in East Asian contexts? To answer this question, Butler and colleagues (2009) compared the emotional responses of Asian American and European American female dyads while they discussed a distressing film. While emotional expression reduced European American participants' cardiovascular arousal (reduced blood pressure), it actually increased Asian American participants' cardiovascular arousal (increased blood pressure). Thus, emotional expression rather than suppression was associated with increased physiological arousal for Asian Americans, a pattern that is the opposite of what cathartic-hydraulic models predict. Similarly, in another study, Mauss and Butler (2010) induced anger in European American and Asian American women. For Asian American women, valuing emotional control was associated with reduced anger experience *and* behavior, and a pattern of cardiovascular responding that is consistent with viewing events as challenges and with more effective emotional control. For European American women, valuing emotional control was also associated with reduced anger behavior, but it was not associated with changes in anger experience. Moreover, valuing emotional control was associated with a

pattern of cardiovascular responding that is consistent with viewing events as threats and with less effective emotional control. In other words, while valuing emotional control appears to be beneficial for Asian Americans, it appears to be harmful for European Americans.

Suppressing emotions may be harder in European American contexts because it runs contrary to the cultural ideal. Indeed Murata, Moser, and Kitayama (2013; Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume) instructed European Americans and East Asians to suppress their emotions in response to negative images. While both groups showed an equally pronounced initial parietal late positive potential (LPP), which is associated with emotional processing, Asians subsequently showed a significant decrease of the parietal LPP in the suppression condition 600 ms poststimulus, and the LPP completely disappeared 2,000 ms poststimulus. In contrast, European Americans exhibited a pronounced and lasting parietal LPP in the suppression condition. These results seem to suggest that for East Asians, who are culturally encouraged (and trained) to down-regulate their emotions, suppressing emotional expression requires fewer resources than it does for European Americans.

Finally, Yuan, Liu, Ding, and Yang (2014) examined the effects of expressive suppression on depressive mood induced by a frustrating arithmetic task in a Chinese sample. Participants were randomly assigned to one of three different instructions before the frustrating task: (1) to suppress (i.e., “Try to control your negative emotional expression”), (2) to accept (i.e., “Let your emotions run naturally”), or (3) to simply perform the task without any further emotional instruction. Participants’ reports of negative affect (distressed, upset, irritable, guilty, ashamed, and depressed) and skin conductance response (SCR) were recorded before, during, and after the frustration task. Participants who were instructed to suppress their emotions reported less negative affect and showed less SCR activity (suggesting less physiological arousal) during the frustrating task compared to participants who were given no emotional instruction or who were asked to accept their emotions. In addition, the participants assigned to the suppression condition showed better emotional recovery after the frustrating task (Yuan et al., 2014). Although this study did not have a Western comparison sample, the results suggest that the effects of suppression on this Chinese

sample were beneficial, which again runs contrary to the Western, cathartic-hydraulic view of emotional suppression.

Another way to assess the value of emotional expression versus suppression is to examine its effects on health. Consistent with cathartic-hydraulic models of emotion, emotional suppression is associated with poor physical health and increased risk for coronary and cardiovascular diseases (Mauss & Gross, 2004) as well as worse psychological health (Aldao, Nolen-Hoeksema, & Schweizer, 2010; Gross & John, 2003; Kashdan, Barrios, Forsyth, & Steger, 2006) and poor social functioning primarily (English & John, 2013; Srivastava, Tamir, McGonigal, John, & Gross, 2009) in U.S. American samples. While some researchers find similar effects in independent and interdependent cultural contexts (English & John, 2013; Roberts, Levenson, & Gross, 2008), more researchers find that culture moderates the effects of expressive suppression on physical and psychological well-being (e.g., Butler, 2012; Butler & Gross, 2009; Butler, Lee, & Gross, 2007; Cheung & Park, 2010; Consedine, Magai, & Bonanno, 2002a; Consedine, Magai, Cohen, & Gillepsie, 2002b; Kwon, Yoon, Joormann, & Kwon, 2013; Lee, Suh, Chu, Kim, & Sherman, 2009; Soto, Perez, Kim, Lee, & Minnick 2011; Su, Lee, & Oishi, 2012). For instance, in one survey, European Americans and Hong Kong Chinese reported their tendency to suppress their emotions (e.g., keep emotions to oneself, control one's emotion by not expressing it), their experience of depressive symptoms over the past few weeks (e.g., feeling lonely, feeling sad, feeling like a failure), and their overall life satisfaction. As expected, suppression was associated with more depressive symptoms and lower life satisfaction for European American but not for Hong Kong Chinese participants (Soto et al., 2011).

Other studies have examined the suppression of specific emotions. In one survey, Cheung and Park (2010) showed that whereas suppressing anger is associated with increased depressive symptoms among both Asian Americans and European Americans, this association was attenuated for East Asian participants, and for participants with more interdependent self-construals. Similarly, in another study, greater reports of anger suppression were more strongly associated with depressive symptoms for U.S. Americans than for Koreans (Kwon et al., 2013). Su and colleagues (2012) took this work one step further, by arguing that the suppression-depression association depends on the type of emotion being suppressed. They

proposed that in East Asian contexts, the suppression of socially disengaging emotions should not be associated with poor psychological functioning, while the suppression of socially engaging emotions should, whereas in European American contexts, the opposite should be true. As predicted, the expressive suppression of socially disengaging emotions, such as pride, was associated with more depressive symptoms for European Americans but not for Chinese Singaporeans. Contrary to predictions, however, no cultural difference was found in the links between the suppression of socially engaging emotions (e.g., respect) and depressive symptoms.

These cultural differences also emerge in specific situations. Le and Impett (2013) found in a daily diary study of an ethnically diverse Canadian sample that the more interdependent individuals were, the more likely they were to report greater well-being and higher relationship quality when they suppressed their negative emotions specifically in adjustment situations (i.e., when they did something they did not like, or when they gave up something they liked for their partner). The opposite relationships emerged for individuals who were low in interdependence.

Interestingly, these cultural differences in the value placed on emotional suppression versus expression may also influence how people process faces. For example, Yuki, Maddux, and Masuda (2007) hypothesized that individuals in interdependent cultures, for whom expressive suppression is valued, should focus more on the eyes and less on the mouth when interpreting facial expressions given that the eyes tend to be more difficult to control than the mouth when expressing emotions (Ekman, Friesen, & O'Sullivan, 1988). On the other hand, individuals in independent cultures, for whom emotional expression is valued, should focus more on the mouth when interpreting facial emotions because it is the most expressive part of the face (Yuki et al., 2007). To test these hypotheses, Yuki and colleagues conducted two studies designed to investigate which parts of the face were crucial when participants were interpreting emoticons (Study 1) and edited expressions of real people (Study 2). In both studies, Japanese weighted the eyes more heavily than did U.S. Americans when making their emotional judgments, whereas U.S. Americans weighted the mouth more heavily than did Japanese when making their emotional judgments. Indeed, in another series of studies, while categorizing different emotions, East Asian participants fixed their attention to the eye region, whereas European

American participants distributed their attention more equally across the face (Jack, Blais, Scheepers, Schyns, & Caldara, 2009; Jack, Garrod, Yu, Caldara, & Schyns, 2012).

In summary, as predicted by independent and interdependent models of self, many Western cultural contexts value emotional expression more and expressive suppression less than do East Asian contexts (see Panel 2, [Figure 11.2](#)). While differences in display rules have been documented for decades, the differential effects of emotional expression and expressive suppression on physiological response and health across cultures have only been established in the last decade (Miyamoto, Yoo, & Wilken, [Chapter 12](#), this volume). Recent research also suggests that cultural differences in the value placed on emotional expression versus suppression results in cultural differences in attention to the eyes rather than the mouth when processing faces, although direct links have yet to be made.

Pattern 3: East Asian Contexts Value Different Affective States Than Western Contexts

Whereas the second pattern in the literature focuses on expressive norms and values, the third pattern in the literature focuses on experiential ideals and values, or how people ideally want to feel, what we refer to as people's "ideal affect." With a few exceptions (Eid & Diener, 2001; Izard, 1971), most research on emotion has focused on how people actually feel, or what we refer to as people's "actual affect." In affect valuation theory (Tsai, 2007), we integrate ideal affect into existing models of emotion by arguing that (1) how people actually feel differs from how they ideally want to feel; (2) culture shapes how people want to feel even more than how they actually feel, whereas temperament shapes how people actually feel more than how they ideally want to feel; and (3) ideal affect shapes what people consciously and unconsciously do to feel good, as well as what decisions they make, how they think about health and well-being, and how they perceive and respond to others. To date, we have documented two main differences in ideal affect between East Asian and Western contexts: (1) East Asians value a balance of positive and negative states more than members of Western contexts, and

(2) East Asians value low-arousal positive states (LAP) more and high-arousal positive states (HAP) less than members of Western contexts.

East Asian Contexts Value a Balance of Positive and Negative States More Than Western Contexts

As mentioned earlier, independent models of the self—particularly in U.S. contexts—privilege differentiating the self from others in positive ways by standing out, being unique, and demonstrating how special one is. In contrast, interdependent models of self—particularly in East Asian contexts—privilege fitting in with others, adjusting to others, conforming to the group, and demonstrating how similar one is to others. These different interpersonal goals have implications for how people want to feel. For instance, although positive emotions might make individuals feel that they are special and better than others, they might also elicit envy from others and make individuals less sensitive to others' needs. While negative emotions might make individuals feel bad about themselves, they might at the same time elicit less envy from others and make people more sensitive to other people's pain. Thus, given their different interpersonal goals, members of Western contexts may want to feel positive more and negative less than members of East Asian contexts do.

Consistent with these hypotheses, we have demonstrated that although most individuals want to feel positive states more than negative ones, the magnitude of this difference varies by culture. Using experience sampling methods in which we asked people to rate how much they actually felt and ideally wanted to feel various affective states at a given moment, we found that European Americans and Chinese Americans wanted to feel positive more and negative less (across all levels of arousal) than did Hong Kong and Beijing Chinese. These cultural group differences were mediated by the degree to which individuals endorsed independent versus interdependent values: The more individuals valued independent over interdependent values, the more they wanted to feel positive more than negative states (Sims, Tsai, Jiang, Wang, Fung, & Zhang, 2015). Importantly, these differences held after we controlled for how much individuals actually felt

negative and positive emotions, demonstrating that cultural differences in ideal affect exist, above and beyond cultural differences in actual affect.

These cultural differences in the desire to maximize positive and minimize negative affect have consequences for affective experience, as well as health and well-being. For instance, numerous studies indicate that in Western contexts, the correlation between positive and negative states is highly negative: The more individuals report experiencing positive emotions, the less they report experiencing negative emotions, both in terms of intensity and frequency. In contrast, in many East Asian contexts (i.e., Chinese, Koreans, Japanese, and Asian Americans), the correlation between positive and negative emotion is consistently less negative, zero, or even positive (Bagozzi, Wong, & Yi, 1999; Goetz, Spencer-Rodgers, & Peng, 2008; Kitayama, Markus, & Kurokawa, 2000; Miyamoto & Ryff, 2011; Perunovic, Heller, & Rafaeli, 2007; Schimmack, 2009; Schimmack, Oishi, & Diener, 2002; Scollon, Diener, Oishi, & Biswas-Diener, 2005; Shiota, Campos, Gonzaga, Keltner, & Peng, 2010; Spencer-Rodgers, Williams, & Peng, 2010b). Many scholars refer to these differences as evidence of the greater experience of “mixed” emotions (co-occurrence of positive and negative emotion) among members of East Asian cultures compared to those of Western cultures.

Although considerable work has demonstrated that cultural differences in mixed emotions are due to cultural differences in “dialectical beliefs,” or the tolerance for contradiction, holism, and acceptance of change (Hui, Fok, & Bond, 2009; J. Kim, Seo, Yu, & Neuendorf, 2014; Spencer-Rodgers, Peng, & Wang, 2010a), we have found that variation in the experience of mixed emotions is also due to differences in ideal affect, independent of dialectical beliefs. As mentioned earlier, we observed that European Americans and Chinese Americans reported wanting to feel positive relative to negative emotions to a greater degree than did Hong Kong and Beijing Chinese. These differences in ideal positive relative to ideal negative affect were related to cultural differences in the experience of mixed emotions: European Americans and Chinese Americans reported fewer mixed emotional experiences than did their Chinese counterparts, and these differences were due to differences in the degree to which individuals wanted to maximize positive and minimize negative affect. To directly assess causality, we experimentally manipulated the desire to maximize positive

and minimize negative by instructing participants to (1) focus only on their good feelings and to ignore any bad ones (i.e., maximize positive and minimize negative more), or (2) focus on the negative feelings (i.e., maximize positive and minimize negative less). Across European American, Chinese American, and Hong Kong Chinese groups, participants experienced fewer mixed emotions during a pleasant television clip when they were instructed to maximize positive and minimize negative more than when they were instructed to maximize positive and minimize negative less (Sims et al., 2015). These findings were not due to dialectical beliefs.

Further support for the role of independent versus interdependent models of self in shaping mixed emotions is provided by Grossmann, Huynh, and Ellsworth (2016) at the country level. They found that more interdependent countries had texts with more mixed emotion sentences (i.e., a positive and a negative emotion in the same sentence). Similarly, in a cross-culturally diverse sample (i.e., India, Japan, Germany, Russia, the United Kingdom, and the United States), individuals in more interdependent countries were more likely to report experiencing mixed emotions than those in less interdependent countries. These findings again held when the researchers controlled for dialecticism, which suggests that interdependence and independence exert a distinct influence on mixed emotional experience.

Research also demonstrates that East Asians are more comfortable with mixed affective experiences (Aaker, Drolet, & Griffin, 2008; Hong & Lee, 2010; J. Kim et al., 2014; Williams & Aaker, 2002), tend to perceive events—especially “positive” ones—as more mixed (e.g., Leu et al., 2010; Miyamoto, Uchida, & Ellsworth, 2010), have more mixed descriptions of happiness (Uchida & Kitayama, 2009), and are more likely to purchase and prefer consumer products (e.g., photo albums, films) with mixed emotional messages (Hong & Lee, 2010; J. Kim et al., 2014) than members of Western cultures are. The degree to which these differences are due to the value placed on maximizing the positive and minimizing the negative, however, has yet to be established.

In addition to mixed emotional experience, empirical findings suggest that cultural differences in the value placed on positive versus negative experience may affect the consequences of experiencing negative and positive emotions for health. A growing body of work has shown that

negative emotions are associated with negative physiological and psychological outcomes (for reviews, see Consedine & Moskowitz, 2007), including increased cardiovascular disease (e.g., Kubzansky & Kawachi, 2000); increased cancer (e.g., Penninx et al., 1998); increased pain, fatigue, and disease (e.g., Geisser, Roth, Theisen, Robinson, & Riley, 2000; Watson, 1988); decreased life satisfaction (Suh, Diener, Oishi, & Triandis, 1998); and even faster mortality (e.g., Pinquart & Duberstein, 2010). Indeed, Pressman, Gallagher, and Lopez (2013) surveyed over 150,000 individuals from 142 countries about their emotions and health, and observed that in both industrialized and developing nations, the more people experienced negative affect, the worse was their health.

While negative affect predicts negative physiological and psychological outcomes across cultures, however, the magnitude of this effect appears to vary across cultures (e.g., Consedine et al., 2002b; Diener & Suh, 2000; Miyamoto et al., 2013; Miyamoto & Ryff, 2011; Miyamoto et al., [Chapter 12](#), this volume). For instance, Curhan and colleagues (2014) compared the effect sizes of the association between negative affect and health in large representative samples of community adults in the United States and Japan. While negative affect significantly predicted poorer health in both samples, negative emotions were more strongly associated with more chronic conditions, worse physical functioning, worse psychological well-being, and lower self-esteem in the United States than in Japan. Similarly, in a large study of emotion and life satisfaction in 46 different nations (Kuppens, Realo, & Diener, 2008), negative emotions predicted poorer life satisfaction more in individualistic than in collectivistic nations. These differences are likely due to the fact that negative affect is more culturally desirable (or less undesirable) in collectivistic nations, although this has yet to be tested directly.

Do such cultural differences emerge when more objective markers of physical health are used? The answer is yes. Higher levels of proinflammatory biomarkers, such as interleukin-6 (IL-6), are believed to be one of the biological pathways that mediate the relationship between negative emotions and health in U.S. samples (Everson-Rose & Lewis, 2005; Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002); however, this appears not to be the case in Japan. Miyamoto and colleagues (2013) examined whether negative emotions predict higher levels of proinflammatory biomarkers

among U.S. Americans and Japanese. U.S. Americans and Japanese rated their negative emotions for the past 30 days, then provided blood samples from which serum IL-6 levels were determined. Whereas negative emotions predicted higher IL-6 among U.S. Americans, they did not for Japanese. In the same sample, Kitayama and colleagues (2015) examined the links between anger expression and biological markers of health in the United States and Japan, and again found that whereas anger expression was associated with increased health risk (as measured by proinflammatory markers such as IL-6 and C-reactive protein, and indices of cardiovascular malfunction such as systolic blood pressure and ratio of total to high-density lipoprotein [HDL] cholesterol) in the United States, the reverse was observed for Japanese. These results remained significant after researchers controlled for age, gender, health status, health behaviors, social status, and reported experience of negative emotions.

Similar findings hold for positive emotions. In the study of emotion and life satisfaction in 46 different nations, described earlier, Kuppens et al. (2008) observed that while positive emotions were more strongly related to life satisfaction than negative emotions across nations, positive emotions had a stronger positive effect on life satisfaction in nations valuing self-expression (e.g., Australia, Canada, the Netherlands, the United States) than in nations valuing survival (e.g., China, Hungary, Russia, Zimbabwe). In yet another study, although reported experience of positive emotions was negatively associated with depression symptoms among European Americans and U.S.-born Asian Americans, the magnitude of the association between positive emotions and depressive symptoms was greater for European American than for Asian American participants (Leu, Wang, & Koo, 2011). Furthermore, the experience of positive emotions was not associated with depressive symptoms for Asian immigrants to the United States.

Finally, cultural differences in the desire to maximize positive relative to negative emotions may explain why East Asians are more likely to dampen their experiences of positive emotion compared to their Western counterparts (Miyamoto & Ma, 2011). For instance, when asked to recall a positive event in their lives, East Asians were less likely to have savored and more likely to have dampened their happiness during the positive event compared with European Americans.

In summary, consistent with independent and interdependent models of self, Western contexts value maximizing positive and minimizing negative emotion more than do East Asian contexts, as illustrated in the third panel (a) of [Figure 11.2](#). These differences have consequences for individuals' likelihood of experiencing mixed emotions. They also potentially explain cultural differences in the links between emotions and health and in how people respond to positive events.

East Asian Contexts Value LAP More and HAP Less Than Western Contexts

Although most people want to feel positive states more than negative states, people vary in terms of the specific types of positive states they ideally want to feel. Again, these differences are related to different models of self: For individuals with independent models of the self, influencing others—changing one's environment to be consistent with one's beliefs, desires, and preferences—is ideal. In order to influence others, people have to act on their environments, and action requires increases in physiological arousal. Therefore, the more people (and cultures) value influence, the more likely they will value HAP such as excitement, energy, and enthusiasm. In contrast, for individuals with interdependent models of self, adjusting to others—changing one's own beliefs, desires, and preferences to be consistent with those of others—is ideal. In order to adjust to others, people have to assess what others want, and then change their own actions to be consistent with what others want. This first requires decreases in action, and decreased action is accompanied by decreases in physiological arousal. Therefore, the more people (and cultures) value adjustment, the more likely they will value LAP such as calm, peacefulness, and serenity (Tamir et al., 2016; Tsai, Knutson, & Fung, 2006; Tsai, Miao, Seppala, Fung, & Yeung, 2007c).

Consistent with these predictions, across a series of studies, we have consistently observed that European Americans report wanting to feel excitement, enthusiasm, and other HAP more than do Hong Kong Chinese, and Hong Kong Chinese report wanting to feel calm, peacefulness, and other LAP more than do European Americans. Chinese Americans, who are oriented to both cultural contexts, value HAP as much as their European

American counterparts, and value LAP as much as their Hong Kong Chinese counterparts (Tsai et al., 2006, 2007c). These differences are reflected in widely distributed products, including children's storybooks, women's magazines, Facebook profile photos, and even the official photos of leaders in government, business, and academia (e.g., Tsai, Louie, Chen, & Uchida, 2007a; Tsai et al., 2016). Moreover, these differences are mediated by cultural differences in influence and adjustment goals. In both survey and experimental studies, across cultures, the more people want to influence others, the more likely they are to value HAP, and the more people want to adjust to others, the more likely they are to value LAP (Tsai, Miao, Seppala, & Fung, 2007c). Again, in all of our analyses, we control for differences in how much people actually feel HAP and LAP, demonstrating that cultural differences in ideal affect exist, above and beyond cultural differences in actual affect.

As predicted by affect valuation theory (Tsai, 2007, 2017), these differences in the value placed on HAP and LAP have important implications for what people do to feel good, how people think about well-being and illness, and how they perceive others. For instance, in their ideal vacations, European Americans describe more exciting and fewer calm activities than do Hong Kong Chinese (Tsai, 2007). When given a choice between calming and exciting music, European Americans are more likely to choose exciting music than are Asian Americans (Tsai, 2007; Tsai et al., 2007c). In another study, we manipulated ideal affect, and then gave participants a choice of exciting versus calming consumer products. Across cultures, participants in the "Value Excitement" condition were more likely to choose exciting versus calming products than those in the "Value Calm" condition were, and across conditions, European Americans were more likely to choose the exciting (vs. calming) products than were Chinese Americans, Beijing Chinese, and Hong Kong Chinese (Tsai, Chim, & Sims, 2015).

These cultural differences in ideal affect also have implications for health and well-being. In Tsai et al. (2006) we observed that for European Americans, Chinese Americans, and Hong Kong Chinese, greater discrepancies between how people actually felt and how they ideally wanted to feel were associated with more depressive symptoms. However, the type of discrepancy that was associated with depression varied across cultures:

For European Americans, discrepancies in actual and ideal HAP predicted depressive symptoms, whereas discrepancies in actual and ideal LAP did not. For Hong Kong Chinese, only discrepancies in actual and ideal LAP predicted depression. For Chinese Americans, who were equally oriented to both cultures, both types of discrepancies were associated with depression. These findings suggest that conceptions of well-being and depression are related to ideal affect. Indeed, when asked to identify the emotions that were centrally associated with depression, European Americans mentioned states that are the opposite of HAP (e.g., dull, bored, and other low arousal negative states; see [Figure 11.1](#)) more than Hong Kong Chinese did, whereas Hong Kong Chinese mentioned states that are the opposite of LAP (e.g., nervous, anxious, and other high arousal negative states; see [Figure 11.1](#)) more than European Americans did (Qu et al., 2018). Similarly, Young, Sims, Charles, and Tsai (2013) observed that whereas for European Americans, increased physical health problems were associated with low-arousal negative states, for Chinese Americans, increased physical health problems were associated with high-arousal negative states.

In recent work, we have examined the effects of cultural and individual differences in ideal affect on how people judge and respond to others. Specifically, we predict that when there is a match between how people want to feel and the emotional expression of a specific target (“ideal affect match”), people will rate that target more positively. Indeed, in a U.S. American sample, we observed that the more people valued HAP, the more trustworthy they rated an excitement-focused physician (i.e., one who promoted an “energetic” lifestyle), and the more they valued LAP, the more trustworthy they rated a calm-focused physician (i.e., one who promoted a “tranquil” lifestyle) (Sims, Tsai, Koopmann-Holm, Thomas, & Goldstein, 2014). Again, all of these findings held after controlling for differences in actual HAP and LAP, demonstrating that ideal HAP and LAP independently predict how people judge others.

In comparisons of European Americans and Hong Kong Chinese, we find that European Americans rate excited targets (regardless of targets’ race or sex) as more affiliative (extraverted, agreeable) compared to Hong Kong Chinese (Tsai et al., 2018a). Furthermore, when given a choice between seeing an excited vs. calm target again, European Americans are more likely

to choose the excited target compared to Hong Kong Chinese (B. Park, Tsai, Chim, Blevins, & Knutson, 2016).

This preference may impact how people respond to others. For instance, in one study, European Americans and Koreans played as the “proposer” in multiple trials of a modified Dictator Game, in which they were given an amount of money and the option of sharing some or even all of that money with their partner (the “recipient”), who had no choice but to accept the offer. During each game, they played with different “excited” and “calm” recipients. European Americans offered more money to excited (vs. calm) recipients, whereas Koreans offered more money to calm (vs. excited) recipients. Moreover, these cultural differences were mediated by how much participants trusted recipients, which was in turn due to how much participants wanted to feel HAP (but not how much they actually felt HAP). These findings suggest that people not only prefer a target whose expressions match their ideal affect but also trust them more, and therefore are more willing to share resources with them (B. Park, Blevins, Knutson & Tsai, 2017). Because these cultural differences held regardless of recipients’ race (White, Asian) or sex (male, female), it is possible that ideal affect match is an even more powerful signal of ingroup membership than race or sex.

In summary, consistent with independent and interdependent models of self, European American contexts value HAP more and LAP less than many East Asian contexts, as illustrated in the third panel (b) of [Figure 11.2](#). These differences have consequences for what people do to feel good, how they think about health and well-being, and how they judge and respond to others. As described below, we are expanding this work to examine cultural differences in the valuation and devaluation of negative states (Koopmann-Holm & Tsai, 2014; Clobert & Tsai, 2018).

Together, a considerable literature conducted primarily over the last decade demonstrates at least two culturally different models of emotion. In the first model that pervades many Western contexts, emotions are more intrapersonally and less interpersonally focused; emotional expression is encouraged and results in a host of beneficial outcomes; individuals value maximizing the positive and minimizing the negative; and individuals are encouraged to feel HAP more and LAP less. In the second model that pervades many East Asian contexts, emotions are less intrapersonally and more interpersonally focused; expressive suppression is encouraged and has

beneficial outcomes; individuals want to feel more of a balance between positive and negative emotions, and individuals want to feel HAP less and LAP more. In order to achieve a broader understanding of emotion and other affective phenomena, both models must be considered in future theory and empirical research.

REAL-WORLD APPLICATIONS

As we mentioned at the beginning of this chapter, cross-cultural studies of emotion were originally conducted to test theoretical models of emotion. However, researchers have also been interested in understanding the influence of culture on emotion for applied reasons as well, and increasingly, research is directly examining these applications. For instance, in our own work, we are examining how cultural differences in ideal affect influence patient-provider interactions in clinical settings. Asian Americans and members of other ethnic/minority groups often report poor patient-provider communication, even when they speak the same language as their health care provider, who is often European American (Ngo-Metzger, Legedza, & Phillips, 2004; Saha, Arbelaez, & Cooper, 2003). To examine whether cultural differences in ideal affect might play a role, European American, Chinese American, and Hong Kong Chinese participants were asked to imagine that their regular primary care provider was no longer available, and that they needed to choose a new provider for their care. Participants were then presented with either an “excitement-focused” or a “calm-focused” physician. European Americans were more likely to choose the excitement- (vs. calm-)focused physician than were Chinese Americans and Hong Kong Chinese, and these differences were mediated by influence versus adjustment goals, and the valuation of HAP versus LAP. These findings suggest that one way to increase communication between patients and their providers may be to pair patients with providers whose expressions match patients’ ideal affect (Sims, Koopmann-Holm, Young, Jiang, Fung, & Tsai, 2017).

Similarly, we have also been interested in whether cultural differences in ideal affect play a role in employment settings. For instance, despite being highly qualified as a group, Asian Americans assume a disproportionately

small percentage of top leadership positions in business, politics, and academia, suggesting that there exists a “bamboo ceiling” (Hyun, 2005). We propose that this bamboo ceiling may be due to cultural differences in the emotions associated with leadership, which may reflect cultural ideals. Based on our own work, U.S. leaders show more excited (open, toothy) smiles in their official photos than do Chinese leaders (Tsai et al., 2016). It is possible that European American employers may not promote Asian Americans to top leadership positions because they are unknowingly using their own cultural ideals of high-arousal positive affect to judge Asian Americans who value LAP. Indeed, in one study, we asked European Americans, Asian Americans, and Hong Kong Chinese to imagine that they were applying for summer internships and to indicate the emotions they wanted to convey in their applications. European Americans reported wanting to convey more HAP (vs. LAP) compared to Hong Kong Chinese. Moreover, European Americans viewed the ideal job candidate as more HAP and less LAP than did Hong Kong Chinese (Bencharit et al., 2018). Asian Americans fell in between the two other groups. And when given a choice between equally qualified excited and calm applicants, European Americans were more likely to choose the excited (vs. the calm) applicant than were Hong Kong Chinese (Bencharit et al., 2018; Tsai et al., 2018a). These findings suggest that cultural differences in ideal affect play a role in work settings and may be particularly important in determining who gets hired.

Cultural differences in ideal affect may also shape prejudice and discrimination (Clobert & Tsai, 2018). Previous research suggests that the more likely individuals are to actually experience high-arousal negative emotions such as anger, fear, or disgust, the more likely they are to hold negative attitudes toward different outgroups such as African Americans and foreigners (Cottrell & Neuberg, 2005; Smith & Mackie, 2010; Vanman, Saltz, Nathan, & Warren, 2004). Furthermore, the more fear people actually feel, the more likely they are to engage in passive harm against outgroups (i.e., avoidance of the outgroup; Mackie, Devos, & Smith, 2000; Skitka, Bauman, Aramovich, & Morgan, 2006), whereas the more anger people feel, the more likely they are to engage in active harm against outgroups (i.e., confrontation with the outgroup; Mackie et al., 2000; Skitka et al., 2006). However, only a handful of studies have examined how the *valuation* of

these states might influence reactions to outgroups (Porat, Tamir, & Halperin, 2016). For instance, Porat et al. examined how preferences for anger versus empathy or anger versus fear influenced endorsement of policies against outgroups. We examined whether the valuation of high-arousal and low-arousal negative affect was related to interpersonal reactions to potential outgroups (e.g., a new family from a different cultural background who moves into the neighborhood). The more individuals valued high-arousal negative affect, the more appropriate they viewed harmful acts against various outgroups (e.g., supporting an initiative asking the new family to move), and the more likely individuals said they would engage in those harmful acts (Clobert & Tsai, 2018). Importantly, these relationships held after we controlled for how much people actually experienced these negative states. One implication of these findings is that, as a culture, we may be inadvertently encouraging people to respond to outgroups in a specific way by encouraging people to feel specific types of negative emotions. Indeed, we found that U.S. newspaper articles about minority groups contained more high arousal negative words than low arousal negative words, as well as more harm words (e.g., attack, hurt, avoid, separate) than facilitation words (e.g., care, help, accept, tolerate) (Clobert & Tsai, 2018). In our current work, we are examining whether cultural differences in ideal negative affect might be related to cultural differences in attitudes toward and responses to outgroups.

In this section, we have described a few ways in which we are examining the implications of cultural differences in ideal affect for different applied settings. Given the increasingly multicultural and global world in which we live, future research should focus on the implications of other cultural differences (e.g., in the focus of emotion and in expressive norms and values) for health, business, and other applied settings.

EMERGING EMPIRICAL TRENDS

Although clear patterns of cultural differences in emotion have emerged that are consistent with independent and interdependent models of self, there are several important trends that promise to reveal other ways in which culture shapes emotion.

Not All Independent and Interdependent National Contexts Are the Same

We have primarily focused on Western and East Asian contexts because they have received the most empirical attention. However, there is considerable variability among different independent and interdependent cultural contexts, and growing research is beginning to explore this variability. For instance, we have compared European American and German views of negative emotion and their consequences for expressions of sympathy (Koopmann-Holm & Tsai, 2014). Although European Americans and Germans share a Western, individualistic heritage, one significant difference between the two groups is how their ancestors responded to economic hardship and religious persecution in Europe. Whereas early American settlers decided to immigrate to the New World in search of a better life, their European counterparts decided to remain in their homelands and adjust to their circumstances. We predicted and observed that these differences in “frontier spirit” are related to views of negative emotion. Indeed, European Americans endorse frontier values more than Germans, and these differences are related to European Americans reporting that they want to avoid negative states more than Germans do. Moreover, these differences in avoided negative affect predicted cultural differences in how people expressed sympathy for another person. When imagining that a close acquaintance has lost a loved one, European Americans were more likely to send a sympathy card that focused on the positive (e.g., “Remembering . . . let time heal your soul”) than one that focused on the negative (“A severe loss . . . take time to grieve”) compared to Germans.

Another example comes from a study comparing U.S. Americans and Belgians. Boiger, De Deyne, and Mesquita (2013a) predicted that anger should be more beneficial to U.S. individualism, which is more competitive, whereas shame should be more beneficial to Belgian individualism, which is more egalitarian. Whereas competitive individualism emphasizes the value of standing out among others, having high self-esteem, and achieving personal success, egalitarian individualism emphasizes the integrity of the individual within a social network of equal rights (Schwartz & Ros, 1995). In this context, although anger is a socially disengaged emotion, it works against egalitarian individualism by emphasizing one’s own desires over the

desires of others. In contrast, shame signals an effort to mend damaged social relationships, which is more consistent with the egalitarian emphasis on conformity and the maintenance of egalitarian relationships. Consistent with these predictions, using experience sampling, U.S. American participants reported experiencing anger more and shame less than did Belgian participants over a period of 7 days.

In the same way that there is heterogeneity among independent contexts, there is considerable heterogeneity among different interdependent contexts (e.g., for emotion in Russian contexts, see Balatsky & Diener, 1993; Chentsova-Dutton, Choi, & Ryder, 2014; Grossman & Kroos, 2010; Lyubomirsky, 2000). While some similar emotional patterns are observed across different interdependent cultural contexts (e.g., engaging vs. disengaging emotions among Japanese and Mexicans compared to European Americans; Savani, Alvarez, Mesquita, & Markus, 2013), some interesting differences in the valuation of affective states exist. For instance, in two studies looking at the valuation of HAP and LAP, Mexican participants showed a significant preference for HAP versus LAP, while Chinese participants showed a preference for LAP over HAP. In those studies, the Mexican pattern of ideal affect looked similar to that of European Canadians (Ruby, Falk, Heine, Villa, & Silberstein, 2012), demonstrating that not all collectivistic contexts share the same ideal affect. Future research is needed to examine the source of differences among various interdependent contexts.

National Differences in Emotion Vary by Age, Gender, and Social Class

Researchers are also beginning to examine how cultural differences at the national level interact with other social categories, such as age, gender, and social class. For example, we observed that the effects of age on ideal affect varied for European American, Chinese American, and Hong Kong Chinese between the ages 18 and 90 (Tsai et al., 2018b). For European Americans, there was no effect of age on ideal affect: Older European Americans wanted to feel as much HAP and LAP as their younger counterparts. In contrast, for Chinese Americans and Hong Kong Chinese, there was a consistent effect of

age on ideal affect: Older Chinese Americans and Hong Kong Chinese wanted to feel less HAP and LAP than their younger counterparts. These cultural differences in the effects of age on ideal affect may reflect cultural differences in ideals of healthy aging, with American ideals focusing on acting young, and Chinese ideals focused on acting one's age. However, in another study, Grossmann, Karasawa, Kan, and Kitayama (2014) found age differences among U.S. Americans (older adults reported fewer negative emotions in unpleasant situations than did younger Americans), but not among Japanese. Future research is needed to explain why the effects of age may vary across cultures and how this impacts different aspects of emotion.

Another social category is gender. Across different cultures, specific emotional “display rules” seems to prevail for women and men (Brody & Hall, 2008). For instance, women are perceived as and tend to be more emotional than men across several different cultures (Simon & Nath, 2004; Timmers, Fischer, & Manstead, 2003). However, gender also interacts with culture. Although women reported more intense emotions and more overt emotional expressions than men in 37 countries (Fischer & Manstead, 2000), the magnitude of gender differences in the intensity of experiences and expressions of joy, shame, disgust, and guilt were greater in countries with higher levels of individualism and gender equality (which are positively correlated; Brandt & Henry, 2012). Follow-up research is needed to examine why this might be.

Finally, an increasing number of researchers are examining the effects of social class on emotion (Kraus, Côté, & Keltner, 2010; Kraus, Piff, & Keltner, 2009). Because working-class contexts endorse more interdependent and less independent models of self than do middle-class contexts (Snibbe & Markus, 2005; Markus & Hamedani, [Chapter 1](#), this volume), working-class individuals should show emotional patterns that are similar to those of East Asians. Indeed, Kraus and colleagues (2009) found that when asked to rate a target's emotional expression, lower-class participants took the faces of the background figures into greater account than did upper-class individuals (Kraus et al., 2010). However, social class also appears to interact with national culture to shape emotional expressions and other domains such as health (for a discussion, see Ryff et al., 2015). For instance, in one study investigating the role of both social status and culture in the expression of anger, J. Park and colleagues (2013) showed that Americans with lower (vs.

higher) social status (measured both objectively and subjectively) expressed more anger, while Japanese adults with higher (vs. lower) social status expressed more anger. It is possible that in the United States, individuals with lower social status report more anger due to frustrations associated with unequal access to resources, whereas in Japan, individuals with higher social status have license to act against cultural ideals and therefore express anger. Another possibility is that in interdependent cultures, only individuals with elevated status in the hierarchy are allowed to enforce norms, in which case the expression of anger may be useful. Again, more research is needed to test these possible explanations more directly.

Religious Cultures Influence Emotion

Like national culture, religion may also be conceived as a cultural system or a form of culture (A. Cohen, 2009; Saroglou & Cohen, 2013; A. Cohen & Neuberg, [Chapter 32](#), this volume) that shapes people's emotions (Tsai, Koopmann-Holm, Ochs, & Miyaki, 2013). Individuals who are religious are more interdependent than those who are not (A. Cohen & Rozin, 2001; Cukur, de Guzman & Carlo, 2004; Triandis, 1995, p. 83). But religions also vary in their degree of independence and interdependence, perhaps depending on whether they are monotheistic (more independent) or nontheistic (more interdependent). Indeed, in previous work, we observed that individuals who identified with a religion (Christianity or Buddhism) valued LAP more than those who did not. However, Christians valued HAP more and LAP less than did Buddhists (Tsai, Miao, & Seppala, 2007b). Using text content analyses, we also observed that HAP were more frequently encouraged in Christian texts and self-help books than in Buddhist classical texts and self-help books. These findings parallel documented cross-cultural differences in the valuation of HAP versus LAP in U.S. American (primarily Christian) versus East Asian (primarily Buddhist) cultures (Tsai et al., 2006).

Similarly, Kim-Prieto and Diener (2009) investigated the desirability of nine discrete emotions (i.e., happiness, love, gratitude, pride, sadness, anger, guilt, shame, and jealousy) and found that Christians experienced and wanted to experience love more frequently than did Muslims and Buddhists. Muslims reported experiencing and wanting to experience sadness and

shame more than did Christians, Buddhists, Jews, and Hindus. Finally, Buddhists reported fewer peaks or dips for any emotion compared to Christians, Jews, Muslims, and Hindus (Kim-Prieto & Diener, 2009).

More recent work has even explicitly tested some of Freud's assumptions about the suppression of emotion in different religions. For instance, in a series of studies, E. Kim, Zeppenfeld, and Cohen (2013) examined the suppression of anger and its consequences for "sublimation," which Freud defined as the rechanneling of unacceptable urges into creative pursuits (Freud, 1905/2000). Protestant, Catholic, and Jewish participants were asked to recall an anger-provoking incident and suppress thinking about it, to recall an anger-provoking incident and suppress thinking about another innocuous topic (e.g., a horse), or to recall a neutral event and suppress thinking about an innocuous topic. After the manipulation, participants engaged in several creative tasks (e.g., creating a sculpture, writing captions for cartoons, making a collage). As predicted, Protestants who recalled an anger-provoking incident and then suppressed thinking about it produced the most creative (and the angriest) work, as rated by expert judges. However, suppressing anger had no effect on creativity for Catholic and Jewish participants. These findings suggest that the usefulness of emotional suppression and the product or consequences of suppressed emotions may also vary across religions. Future studies should not only broaden studies of emotion across different religions but also examine whether religious differences in independence and interdependence account for some of this variation.

Immigrants Emotionally Acculturate to Their Host Cultures

Although decades of research have examined how immigrants acculturate to their host cultures as a way of understanding socialization processes, few researchers have examined acculturative processes in the domain of emotion. Mesquita and colleagues have demonstrated that the more Korean immigrants in the United States and Turkish immigrants in Belgium engage in their host cultures, the more their emotional patterns overlap with that of their host cultures (e.g., De Leersnyder, Mesquita, & Kim, 2011, 2013; see

Mesquita, De Leersnyder, & Jasini, [Chapter 19](#), and Morris, Fincher, & Savani, [Chapter 18](#), this volume). Similarly, Consedine and colleagues surveyed immigrant women in the United States from various regions (i.e., Haiti, the Dominican Republic, the English-speaking Caribbean and Eastern Europe). More time spent in the United States predicted a greater emotional similarity between the immigrants and members of U.S. culture. Moreover, emotional acculturation seems to be highly functional for immigrants and has positive consequences for both physical and psychological well-being (e.g., Consedine, Chentsova-Dutton, & Krivoshekova, 2014; De Leersnyder, Kim, & Mesquita, 2015; De Leersnyder, Mesquita, Kim, Eom, & Choi, 2014). For example, individuals who displayed greater cultural fit (i.e., fit between the immigrant's and the host culture's emotional patterns) had greater levels of relational well-being (De Leersnyder et al., 2015). Interestingly, in another study, these authors observed that emotional fit predicted psychological well-being but only in culturally desirable situations (i.e., autonomy-promoting situations in the United States, relatedness-promoting situations in Korea, and both in Belgium) (De Leersnyder et al., 2015).

Increasing research is also examining how immigrants emotionally switch between their native cultures at home and their host cultures at school or work. Indeed, the emotional patterns of Korean and Turkish immigrants in the United States and Belgium, respectively, fit the emotional patterns of Korean and Turkish natives when immigrants are at home, but fit those of Americans and Belgians when immigrants are at work, respectively (De Leersnyder, Kim, & Mesquita, 2018). These findings suggest that immigrants and other bicultural individuals consciously or unconsciously switch emotionally depending on the situation. Future research should examine how this process occurs, and what factors facilitate or hinder these processes.

Other Cultural Factors Influence Emotion

Although most research has focused on cultures that differ in terms of independence and interdependence, new research is examining other cultural factors as well. For example, Niedenthal and colleagues have begun to examine the links between national differences in historical heterogeneity,

or “the extent to which a country’s present-day population descended from migration from numerous vs. few source countries over a period of 500 years” (Rychlowska et al., 2015, p. 2429) and emotional expression. Whereas members of historically homogeneous societies share common norms, language, and practices, members of historically heterogeneous societies by definition do not. Thus, Rychlowska et al. (2015) argued that in order to convey their feelings accurately, members of historical heterogeneous societies must amplify their emotional expressions in order to be accurately read by others. In a reanalysis of data on display rules in over 32 countries (Matsumoto, Yoo, & Fontaine, 2008), the more historically heterogeneous a country was, the more individuals believed that emotions should be openly expressed versus suppressed (Rychlowska et al., 2015), and the more individuals believed that smiling served social bonding versus status signaling functions (Rychlowska et al., 2015).

Neuroscience Methods Reveal How Culture Influences Emotion

Finally, although neuroscience methods have been used to study various emotional phenomena, researchers have only recently begun using them to study culture (e.g., Chiao et al., 2008, Han & Northoff, 2009). Cultural neuroscience is an emerging field that examines how cultural ideas and practices shape genetic and neural processes related to emotion, and how neurobiological mechanisms shape engagement in and transmission of cultural ideas and practices (for a review, see Chiao, 2009; Chiao et al., 2013; Rule, Freeman, & Ambady, 2013; B. Park et al., 2016). For instance, to examine the specific mechanisms that drive cultural differences in social preference, we had European Americans and Chinese view and then rate excited versus calm targets that varied in terms of race (White, Asian) and sex (male, female) in a magnetic resonance scanner (B. Park et al., 2016). As expected, we found cultural differences in activity in brain regions associated with affect and reward (i.e., bilateral ventral striatum and left caudate nucleus) suggesting that compared to European Americans, Chinese found the excited (vs. calm) faces to be less rewarding, regardless of the target’s race or sex. In addition, Chinese showed greater activity in brain

regions associated with identity and self-relevance (i.e., medial prefrontal cortex) when viewing calm Asian faces. These findings suggest that when people view faces that match their cultural ideal, they find the faces more rewarding and identify with them more (B. Park et al., 2016). Thus, culture shapes neural responses associated with affective and higher order cognitive processes.

Other researchers are examining the interaction of culture and genetics (e.g., Chiao & Blizinsky, 2010; H. Kim et al., 2010, 2011; Kitayama et al., 2014). For instance, H. Kim and colleagues (2010, 2011) examined whether individuals with a genetic predisposition toward socioemotional sensitivity (i.e., those homozygous for the G allele of the OXTR rs53576 site on the oxytocin receptor gene) were more likely to adhere to cultural norms of emotion regulation in South Korea and the United States. As expected, they showed that individuals who were genetically predisposed to be more sensitive to socioemotional information (GG genotype) reported using emotional suppression more than those who were genetically predisposed to be less sensitive to socioemotional information (AA genotype) among the Korean sample. In contrast, European Americans with the GG genotype reported using emotional suppression less than did those with the AA genotype. These studies suggest that individuals with specific genetic predispositions may be more likely both to endorse and to adhere to dominant cultural norms and values. Again, future research will reveal whether these trends (and the others described earlier) hold over time.

CONCLUSION

Over the last decade, considerable empirical research has demonstrated the existence of two models of emotion. One stems from independent views of the self and pervades Western cultures; the other stems from interdependent views of the self and pervades East Asian cultures. These two models of emotion differ in their focus of emotion (intrapersonal vs. interpersonal), the value they place on expression versus suppression, the degree to which they value maximizing the positive and minimizing the negative, and the degree to which they value high versus low arousal positive states. Scientists studying emotion need both models to broaden their understanding of

emotion and other affective processes, and teachers, employers, and clinicians need both models to understand the role that culture plays in the everyday lives of their students, employees, and patients. Emerging trends suggest myriad other ways in which culture shapes emotion and other affective processes, which will reveal themselves in the decades to come.

ACKNOWLEDGMENTS

Preparation of this chapter was funded by National Science Foundation Grant No. BCS-132446 awarded to Jeanne Tsai, and by Belgian American Education Foundation and Belgian National Fund for Scientific Research fellowships awarded to Magali Clobert. We thank Elizabeth Blevins, BoKyung Park, Lucy Bencharit, Hazel Markus, Dov Cohen, and Shinobu Kitayama for their very helpful comments on multiple drafts of this chapter.

CHAPTER 12

Well-Being and Health

A Cultural Psychology of Optimal Human Functioning

Yuri Miyamoto, Jiah Yoo, and Brooke Wilken

In this chapter, we aim to integrate the existing evidence on the cultural grounding of well-being and health and to delineate a cultural approach to understand optimal human functioning. The theoretical framework of a cultural approach is presented at the beginning. Building on this framework, we first review findings on cultural differences in conceptualizations of well-being and health. We then provide an overview of evidence on cultural differences in predictors of well-being and health. Subsequently, we review studies that show how cultural contexts and social structural factors (i.e., social hierarchy) work together and sometimes interact with each other to influence well-being and health. Future directions are discussed at the end.

Cultural meaning systems provide individuals with beliefs and ideas about what is “good,” “true,” and “right” (Fiske, Kitayama, Markus, & Nisbett, 1998; Markus & Kitayama, 1991; Shweder, 2003; Triandis, 1989). Such cultural systems can shape how individuals view, experience, and strive for a good life and “optimal functioning” (which we define here as well-being and health). Thus, cultural contexts play a pivotal role in shaping optimal human functioning. In this chapter, we first propose and outline a cultural approach to the study of optimal human functioning. We then review findings on cultural differences in the meanings of well-being and health, and cultural

influences on predictors of, and pathways to, well-being and health. Subsequently, we review a social structural factor, namely, social hierarchy, that has been shown to influence well-being and health; in particular, cultural contexts influence and moderate the meaning of social hierarchy and its effects on well-being and health. We conclude with future directions.

APPROACHES TO WELL-BEING AND HEALTH

To situate a cultural approach, we first review existing influential approaches to well-being and health, and the role culture plays, or does not play, in each approach. We then outline a cultural approach to examining well-being and health.

Hedonic versus Eudaimonic Approaches to Well-Being

Researchers often conceptualize well-being as involving hedonic and/or eudaimonic aspects (Ryan & Deci, 2001). From a hedonic approach, “well-being” is construed mainly as happiness or attainment of pleasure and avoidance of pain. One of the most common ways to assess well-being in this approach is to measure one’s cognitive and affective evaluation of life, termed “subjective well-being” (SWB), which consists of life satisfaction, positive affect, and negative affect (Diener, 1984). On the other hand, from a eudaimonic perspective, well-being is conceived of as not just happiness or hedonic pleasure; well-being rests on the striving for, and realization of, one’s true potentials in a way that fosters purpose in life (Ryan & Deci, 2001; Ryff & Singer, 1998; Waterman, 2007). Researchers who take a eudaimonic approach measure the actualization of human potential in certain proposed domains, such as autonomous engagement, positive relations to others, and purposeful living (Ryan & Deci, 2001; Ryff, 1989). However, research based in the eudaimonic approach often utilizes SWB as well, as either an indicator of well-being or as its consequence or by-product.

These different perspectives on well-being provide different ways to view cultural influences on well-being. From a hedonic perspective, cultural differences may exist in the extent to which cultures fulfill certain sources of

well-being (e.g., wealth) or which sources (e.g., self-esteem) matter more for well-being. Thus, researchers who take a hedonic perspective often focus on cultural differences in levels and correlates of subjective well-being (Diener, Oishi, & Lucas, 2003). The assumption underlying this approach is that even though there may be cultural differences in specific standards or sources of well-being, SWB provides a summary of the extent to which one is succeeding at achieving whatever standards are used in one's cultural contexts (Diener & Suh, 2000). Similarly, a eudaimonic view assumes that cultural contexts shape which specific activities are considered to be meaningful and essential for a good life (Ryff & Singer, 1998), while also proposing that core features of a good life at the general level are fundamentally "good" in all cultures (Ryan & Deci, 2001; Ryff & Singer, 1998). Thus, researchers who take a eudaimonic view often identify cultural similarities in the core features of eudaimonic well-being (e.g., Chirkov, Ryan, Kim, & Kaplan, 2003) or focus on the manifestation of these core features of eudaimonic well-being within a specific culture (e.g., *ikigai*, or a sense of life worth living in Japan; Sone et al., 2008).

Biomedical versus Biopsychosocial Approaches to Health

There also have been two different models of health. The biomedical model of health, which has been the traditional view employed in medical science for at least the past 300 years, argues that illness can be fully explained by abnormal biological processes, an idea that reflects assumptions that the mind and body are independent from each other and that the "mind" can be ignored (Engel, 1977). In contrast, the biopsychosocial model of health maintains that health is based on the interactions between biological, psychological, and sociocultural factors. Such a biopsychosocial model argues for the importance of understanding individuals and their health in an interrelated system that integrates micro-level biological processes (e.g., tissues, cells), psychological level processes (e.g., experience, beliefs, behavior), and macro-level social processes (e.g., culture, society; Engel, 1977).

These two models have different views on the role of culture in health processes. Whereas sociocultural contexts play no real role in the etiology of disease according to the biomedical model of health, the biopsychosocial model incorporates sociocultural contexts into its systems theory. However, even in the field of health psychology, a field that is based on the biopsychosocial model, the amount of attention paid to cultural contexts has been relatively limited (Landrine & Klonoff, 1992).

A Cultural Approach to Optimal Functioning

A cultural-psychological approach starts with the notion that optimal human functioning is fundamentally grounded in cultural meaning systems (Fiske et al., 1998; Markus & Kitayama, 1991; Shweder, 2003; Triandis, 1989). As depicted in [Figure 12.1](#), cultural beliefs and values about optimal functioning have been ecologically and historically derived (“distal-level sociocultural processes”) and have been accumulated in institutions, practices, and products (“proximal-level sociocultural processes”) that shape, and are shaped by, the individuals who participate in them (“psychological processes”). By individuals’ repeatedly engaging with these cultural contexts, cultural beliefs and values about optimal functioning become readily accessible and natural to them. Furthermore, once these ways of viewing and experiencing optimal functioning become natural and habitual to individuals, they can serve to maintain and reinforce cultural meaning systems.

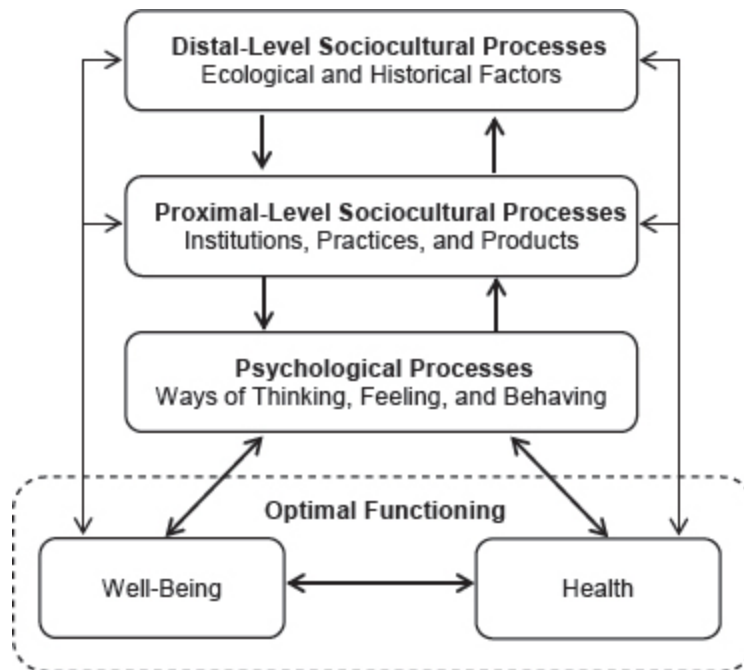

FIGURE 12.1. Cultural models of optimal functioning.

Building on this framework, researchers with a cultural approach often start by exploring and understanding the meaning of optimal functioning in the pertinent culture. They often do so by examining people’s lay beliefs about what a good life, happiness, or health means in their own cultural contexts. Moreover, they often examine how these different meanings and sources of optimal functioning are associated with, and manifest as, actual human functioning across cultures. Although researchers who take a cultural approach do not deny the possibility that certain facets or sources of optimal functioning are universally important, they tend to start with a bottom-up approach to understand the meanings and manifestations of optimal functioning in each cultural meaning system, rather than applying a model or theory established in one culture to another.

Our intention in this chapter is to integrate the existing evidence on cultural shaping of psychological and physical functioning to provide support for a comprehensive cultural approach to optimal functioning. Special emphasis is given to our findings based on data from the Midlife in the United States (MIDUS) and the Midlife in Japan (MIDJA) studies that drew representative samples from the United States and Japan. Both studies included a wide range of psychosocial variables and health measures.

Furthermore, subsamples of respondents also provided comprehensive biological measures of health (i.e., biomarker subsamples). Thus, these studies provided us with a unique opportunity to examine well-being and health among members of a representative sample across cultures.

CULTURAL DIFFERENCES IN THE MEANING OF WELL-BEING AND HEALTH

Cultural Differences in the Meaning of Well-Being

Independent versus Interdependent Views of Well-Being

Although many dimensions have been proposed to characterize different cultural meaning systems, one of the most widely documented ways in which cultures differ from each other is whether a person is considered to be an independent entity defined by his or her internal attributes that are separated from social contexts, or an interdependent entity fundamentally embedded in social relationships and contexts (Markus & Kitayama, 1991; Triandis, 1989). The former has been suggested to characterize the view of personhood in Western culture, whereas the latter has been suggested to be dominant in many non-Western cultures, such as East Asian cultures. These different views of personhood likely shape how well-being is construed in each culture.

In fact, historians, linguists, and psychologists have suggested that the meaning of happiness differs across languages, religions, cultures, and time (Joshnloo, 2014; McMahon, 2006; Uchida, Norasakkunkit, & Kitayama, 2004; Wierzbicka, 2004). Recent analyses of present-day dictionaries across 30 nations and historical dictionaries within the United States (Oishi, Graham, Kesebir, & Galinha, 2013) demonstrated that, in most cultures, definitions of “happiness” included good luck, which relies on external circumstances; however, over the course of history in the United States, the definition of “happiness” has shifted from external luck to focus on positive inner feelings. Such findings suggest that in independent cultural contexts such as the United States, where individuals are defined primarily by their

internal attributes, independent of social contexts, “happiness” is also defined by internal states that individuals can control, pursue, and attain by themselves.

In contrast to the importance of positive internal states for the concept of happiness in independent cultural contexts, social relationships have been shown to be crucial in interdependent cultural contexts (Lu & Gilmour, 2006; Uchida & Kitayama, 2009). For example, by asking participants to freely describe features of happiness, Uchida and Kitayama found that positive hedonic experience was closely associated with personal achievement in Americans’ conceptualization of happiness, whereas positive hedonic experience was more closely associated with social harmony in the Japanese conceptualization of happiness. Reflecting these cultural differences in lay beliefs about happiness, in comparison to Chinese, Americans have been shown to more strongly endorse an individual-oriented conceptualization of SWB that emphasizes both a personal responsibility for and an active pursuit of happiness, whereas Chinese tend to endorse a more social-oriented conceptualization of SWB that emphasizes fulfillment of role obligations than do Americans (Lu & Gilmour, 2006).

The divergent views of personhood may also influence what *kinds* of positive emotions are considered to be ideal and important for well-being. For example, Chow and Berenbaum (2012) showed that people who score high on independence tend to believe that self-centered positive emotions (e.g., pride) facilitate attainment of important goals in their lives, and people who hold such beliefs are more likely to consider these emotions to be ideal. In contrast, people who score high on interdependence tend to perceive other-centered positive emotions (e.g., appreciation) to facilitate goal attainment, and people with such beliefs are more likely to view those emotions as ideal. Moreover, the arousal level of positive emotions has also been shown to matter. Tsai, Knutson, and Fung (2006) have demonstrated that high arousal positive emotions (HAPs; e.g., excited, elated) are considered to be more ideal by European Americans than they are by Asians and Asian Americans, whereas low arousal positive emotions (LAPs; e.g., calm, peaceful) are considered to be more ideal by Asians and Asian Americans than they are by European Americans.

There are also differences among interdependent cultures. Although both Hispanic cultures and East Asian cultures are considered interdependent cultures (Triandis, 1989), a cultural script called *sympatía* characterizes interdependence in Hispanic culture but not in East Asian culture; this script promotes social harmony through open and vibrant expression of positive emotions (Triandis, Marín, Lisansky, & Betancourt, 1984; Levine, Harrington, & Uhlmann, [Chapter 23](#), this volume). Reflecting this cultural script, Mexicans prefer HAP over LAP—a pattern closer to that of European Americans than to that of East Asians (Ruby, Falk, Heine, Villa, & Silberstein, 2012). Thus, interdependence may manifest differently depending on other ecological or historical factors.

Dialectical versus Nondialectical Views of Well-Being

In addition to independent and interdependent views of personhood, dialectical beliefs have also been shown to characterize different cultural meaning systems (Masuda, Russell, Li, & Lee, [Chapter 8](#), and Nisbett, [Chapter 7](#), this volume; Peng & Nisbett, 1999; Spencer-Rodgers, Williams, & Peng, 2010; Wilken & Miyamoto, 2018a). Dialectical beliefs have been historically more prevalent in East Asian culture and are rooted in Daoism, Buddhism, and Confucianism (Joshanloo, 2014; Lu, 2001). According to a dialectical worldview, reality is a dynamic, ever-changing process full of contradictions, in which two sides of a contradiction, such as happiness and unhappiness, coexist in balance and are constantly changing into each other. Such dialectical beliefs about the nature of the world may also shape how well-being is conceived of and experienced.

Reflecting these dialectical beliefs, studies have shown that Easterners' conceptualization of happiness involves its relationship to unhappiness. Qualitative analyses of Taiwanese and Japanese definitions of happiness showed that happiness and unhappiness are conceived of as relative, constantly changing, and interdependent (Lu, 2001; Uchida & Kitayama, 2009). However, a dialectical view of happiness was rarely reported among Americans (Lu & Gilmour, 2004; Uchida & Kitayama, 2009). This belief about the interchangeable nature of happiness and unhappiness is also evident in views of one's life. When asked to choose the graph that best

represents the course of happiness in their lifetime, Americans were more likely than were Chinese to choose graphs that depicted linear trends (i.e., happiness either was increasing or decreasing over their lifetime at a steady pace), whereas Chinese were more likely than were Americans to choose graphs that depicted nonlinear trends (e.g., a U-shaped curve in which happiness changes into to unhappiness, which in turn changes into happiness), suggesting that Chinese are more likely than Americans to perceive happiness and unhappiness to be more dynamic processes that transform into each other (Ji, Nisbett, & Su, 2001).

Dialectical beliefs are also reflected in views of positive and negative emotions, which are components of SWB (Diener, 1984). According to dialectical beliefs, two sides of a contradiction, such as positive emotions and negative emotions, are interdependent and constantly changing into each other. In line with these dialectical beliefs, East Asians are more likely than Americans both to believe that positive emotions are transient and change into negative emotions (Miyamoto & Ma, 2011) and to perceive positive utilities of negative emotions, such as motivating one to work harder or helping one to focus (Miyamoto, Ma, & Petermann, 2014). Dialecticism is also evident in the desirability of positive and negative emotions. Chinese were more likely than Americans or Australians to consider positive emotions such as pride and contentment to be undesirable (Eid & Diener, 2001). Negative emotions are also considered to be more personally and socially undesirable in Australia than they are in Japan (Bastian et al., 2012). Furthermore, Chinese were less likely than Americans were to consider the maximization of positive emotions and the minimization of negative emotions to be ideal (Sims et al., 2015). These findings suggest that positive emotions are valued less and negative emotions are valued more in East Asian culture than they are in Western culture.

These dialectical views of happiness and positive emotions are not confined to East Asian cultures. By comparing 15 cultures with a country-level analysis, Joshanloo and colleagues (2015) show that, compared to people coming from more individualistic (and therefore more independent) cultures (e.g., the United States and the Netherlands), people coming from less individualistic (and therefore more interdependent) cultures, including East, Southeast, and South Asian cultures (e.g., Pakistan and Malaysia), tend

to believe that happiness is fragile and tend to fear that happiness, especially an excess of it, can lead to bad consequences. There are two important implications of these findings. First, they show that dialectical views of happiness are not limited to East Asia. Second, at a country-level, interdependence is positively associated with dialectical views of happiness. It is therefore possible that these two broad dimensions of cultures (i.e., independence vs. interdependence and dialectical vs. nondialectical views) are not completely independent of each other, but that they are sometimes mutually reinforcing. People in interdependent cultures in which the maintenance of social harmony is imperative do tend to be more concerned about the interpersonal ramifications of their happiness than do people in independent cultures (Miyamoto, Uchida, & Ellsworth, 2010; Uchida & Kitayama, 2009). Thus, the interpersonal concerns that are highlighted in interdependent cultures may sometimes foster dialectical views of happiness by making people fear the negative interpersonal effects of happiness. At the same time, the association between interdependence and dialectical views is not deterministic, since certain interdependent cultures (e.g., Brazil) do not hold dialectical views (Joshani et al., 2015), and some effects of dialecticism cannot be explained by interdependence (Miyamoto & Ma, 2011). As we mentioned in the previous section, it is possible that other factors also sometimes play a role.

Cultural Differences in Levels of Well-Being

One implication for cultural differences in meanings and models of well-being is that they may lead to cultural differences in *levels* of well-being. International surveys have shown that the level of SWB differs across cultures (e.g., Inglehart & Klingemann, 1999). Various sociodemographic factors, such as income, civil rights, and social equality, have been shown to account for cross-cultural variations in levels of SWB (Diener, Diener, & Diener, 1995). However, sociodemographic factors cannot explain why certain cultures that are wealthy and democratic (e.g., Japan and South Korea) show moderate or even lower levels of SWB. In addition to sociodemographic factors, individualism has also been shown to predict SWB (Diener et al., 1995). Nations that are higher on individualism tend to

have a higher SWB, potentially because people may be less concerned about possible negative interpersonal ramifications of happiness in individualistic cultures (Miyamoto et al., 2010; Uchida & Kitayama, 2009). In addition, people in individualistic cultures have been suggested to have self-serving biases and perceive themselves positively (Heine, Lehman, Markus, & Kitayama, 1999), which leads them to perceive their own lives positively, too (i.e., high SWB).

Dialectical views are also playing a key role in cultural variations in levels of well-being. In a country-level analysis, nations with higher dialectical beliefs about happiness (i.e., happiness is perceived to be fragile and to lead to negative consequences) tend to have a lower level of life satisfaction (Joshani et al., 2015). On the other hand, nations in which positive emotions are more valued (reflecting more nondialectical views of emotions) tended to have a higher level of life satisfaction (Bastian, Kuppens, De Roover, & Diener, 2014). Individual-level analyses have also shown that having dialectical views about emotions can lead one to actually experience less positive emotions and more negative emotions (Miyamoto & Ma, 2011; Miyamoto et al., 2014; Sims et al., 2015; see also Koo & Suh, 2007). For example, dialectical beliefs about positive emotions led Asians to try to dampen their positive emotions after a positive event, which in turn made them experience less positive emotion over time compared to Americans (Miyamoto & Ma, 2011). Thus, dialectical views seem to contribute to both cultural-level and individual-level variations in SWB.

Regardless of the source, cultural differences in levels of well-being tend to be larger when the judgement of well-being is based on global, retrospective measures (e.g., “How good or bad was the week?”) than on specific, online measures (e.g., “How good or bad was today?”; Oishi, 2002). This is likely because responses to the former types of measures are more likely to be influenced by cultural beliefs than are responses to the latter, which are based more on experiential and contextual factors (Robinson & Clore, 2002).

Cultural Differences in Views of Health and Illness

Independent versus Interdependent Views of Health and Illness

The biomedical model of health, which views illness to be caused primarily by abnormalities in biological processes independent of psychological and social processes, is not only the dominant view of Western medical professionals, but it is also the predominant view held by laypeople in modern Western society (Fabrega, 1975). However, studies in medical anthropology and sociology have documented that the biomedical model of health is not shared by all cultures (for a review, see Landrine & Klonoff, 1992); whereas illness is construed primarily as an intrapersonal event caused by natural environmental factors (e.g., genes, viruses) in European American culture, in Latin America and Africa, illness has traditionally been construed as being more of an interpersonal process resulting from violations of interpersonal norms, social roles, and moral standards.

Cultures also differ in whether distress is framed and expressed in terms of psychological states (i.e., psychologization) or somatic states (i.e., somatization). By examining psychiatric outpatients in Canada and China, Ryder and colleagues (2008) showed that whereas Canadian outpatients tend to report more psychological symptoms (e.g., depressed mood, feelings of worthlessness) than somatic symptoms, Chinese outpatients tend to report more somatic symptoms (e.g., sleep problems, poor appetite, headache) than psychological symptoms. These cultural differences seem to parallel cultural differences in the conceptualization of well-being: In independent cultural contexts, where well-being is conceptualized mainly as a positive internal psychological state, distress may also be more likely to be conceptualized and to manifest as internal psychological states. On the other hand, in interdependent cultural contexts, internal psychological states may play less prominent roles in defining either well-being or distress.

Dialectical versus Nondialectical Views of Health and Illness

Another aspect of the biomedical and Western model of health is its dualistic view of mind and body (Engel, 1977; Fabrega, 1975). Reflecting this

view, psychiatric illness has been distinguished from nonpsychiatric illness and treated differently in Western medicine. In contrast, in Chinese medicine, there has been less interest in distinguishing different types of illness, because the focus is placed more on differentiating clusters of symptoms, which are assumed to reflect an imbalance that could have various causes. Thus, the sharp distinction between mental and physical illness that exists in Western medicine does not seem to be as sharp in Chinese medicine (Fabrega, 1990).

On the other hand, the concept of balance underlies views of health in many cultures, including Western culture, at least in the past (Manderson, 1987). In ancient Greece, Hippocrates formalized the humoral theory of the human body, which poses that the human body contains four types of body liquids (“humors”) and that an optimal balance between these four humors is essential for health. Having too much or too little of one of the humors was thought to result in illness, and treatment was designed to restore balance among the humors. A similar humoral theory of health also existed in ancient China and India. Although the humoral concept is no longer dominant in contemporary Western cultures, the idea that health rests on a balance among different elements of the body is still prevalent in many parts of the world (Logan, 1975; Manderson, 1987). For example, in many Latin American nations, as well as the Caribbean and the Philippines, health is considered to rest on a balance between hot and cold—symbolic powers that exist in many substances, such as foods and medicinal herbs (Foster, 1987). Similarly, Chinese medicine views a balance between the opposing cosmic principles of yin (e.g., cloudy, earth, night, cold, negative) and yang (e.g., sunny, heaven, day, heat, positive) as essential to health (Veith, 2002).

Beliefs about Health Behaviors

In addition, cultures differ in beliefs and values about health-relevant behaviors such as eating, smoking, and exercise. Such beliefs about health behaviors differ even within Western cultures, and they also change over time (Rozin, 1999; Rozin, Fischler, Imada, Sarubin, & Wrzesniewski, 1999). For example, a cross-cultural study comparing the United States, Japan, Belgium, and France showed that Americans have the most negative

attitudes toward food; they tend to have the most worry about the negative effects of food on health and are the least likely to consider food as a source of pleasure, and this is especially true for American women. These findings might be partly due to American independence and to Protestantism (which emphasizes taking personal responsibility for one's health and body; Rozin et al., 1999). In addition, attitudes toward health behaviors can change within a society over time. Rozin (1999) theorized that culture sometimes moralizes (i.e., imposes moral value on) certain health behaviors that were previously considered to be a matter of preference. For example, although smoking was considered to be a matter of preference in the United States 50 years ago, it now has moral connotations. The process of moralization can happen in the opposite direction, too; marijuana and homosexuality, which once were viewed in moral terms, are increasingly viewed as matters of preference in the United States.

CULTURAL DIFFERENCES IN PREDICTORS OF WELL-BEING AND HEALTH

Independence versus Interdependence as Predictors

Cultural Match

In addition to shaping the meaning of optimal functioning, cultural contexts also influence what predicts and fosters optimal functioning. The majority of research taking a cultural approach, either implicitly or explicitly, assumes that the match between individual psychological processes and culturally prescribed tasks and goals leads to optimal functioning. First, culturally dependent views of personhood shape the kinds of tasks and goals that are highlighted and sanctioned in each culture (Markus & Kitayama, 1991; Triandis, 1989). In Western, independent cultural contexts, culturally prescribed tasks and goals are to realize and express one's unique positive characteristics (H. Kim & Markus, 1999; H. Kim & Sherman, 2007) and to influence the environment according to one's needs (Morling, Kitayama, & Miyamoto, 2002). In Eastern, interdependent cultural contexts, culturally prescribed tasks and goals are to fit into one's roles and others' expectations,

and to maintain harmonious relationships. Second, because engaging in culturally prescribed ways of living should make one feel “good,” “right,” and “agentic” (Fiske et al., 1998; Markus & Kitayama, 2003; Miller, 2003; Shweder, 2003), thinking, feeling, and acting in ways that fit culturally prescribed tasks and goals are theorized to lead to better functioning (Mesquita, De Leersnyder, & Albert, 2014; Markus & Kitayama, 1994; Oyserman, Fryberg, & Yoder, 2007). Specifically, thinking, feeling, and acting in ways that are congruent with culturally prescribed tasks should make individuals feel natural and good, and should feel rewarding both personally and socially. This process should in turn lead to better psychological functioning.

Consistent with this theorization, Oishi and Diener (2001) found that there is a link between the attainment of culturally prescribed goals and well-being. They showed that although the attainment of goals predicted an increase in SWB across cultures, the reasons for pursuing particular goals moderated the effect; that is, pursuing goals for an independent reason (i.e., to have fun and enjoyment) increases the benefit of goal attainment on SWB among European Americans but not among Asian Americans, whereas pursuing goals for an interdependent reason (i.e., to make family and friends happy) increases the benefit of goal attainment on SWB among Asian Americans but not among European Americans. These findings suggest that pursuing and attaining culturally sanctioned goals are conducive to well-being.

Other indicators of engagement in culturally prescribed tasks have also been linked to well-being. Individuals who are engaging in independent, culturally prescribed goals (e.g., those who have positive personal characteristics and personal control) function better than do those who are not engaging in these goals in Western culture. For example, having a sense of personal control and an orientation toward influencing the environment has been linked to higher well-being and lower distress in Western samples than it has in Asian samples (Kitayama, Karasawa, Curhan, Ryff, & Markus, 2010; Mesquita & Karasawa, 2002; Sastry & Ross, 1998). Also, various studies have shown that self-esteem is a stronger predictor of well-being in Western culture than it is in Eastern culture (e.g., Hitokoto & Uchida, 2015; Kwan, Bond, & Singelis, 1997; Uchida, Kitayama, Mesquita, Reyes, & Morling, 2008; but see Novin, Tso, & Konrath, 2014, for cultural

similarities). Other personal characteristics, such as satisfaction with the self (Diener & Diener, 1995) and self-consistency (Suh, 2002), have also been shown to be stronger predictors of well-being in Western than in Eastern cultures.

In contrast, individuals who engage in interdependent, culturally prescribed tasks (e.g., those who experience high relational harmony, adjust to the environment, and fulfill roles and obligations) function better than those who do not engage in such tasks in Eastern culture. For example, the extent to which one achieves relational harmony with close others (Kwan et al., 1997), the extent to which one is relationally oriented and fits the social standard (Hitokoto & Uchida, 2015), the extent to which one receives high emotional support (Uchida et al., 2008) and has low relationship strains (Kitayama et al., 2010) predicts the well-being of Asians more than that of Americans. Other interpersonal tasks, such as obligations to help family and friends (Miller, Das, & Chakravarthy, 2011), also predict well-being in Eastern but not Western cultures.

Although, on the surface, social support may appear to be an interdependent task, the link between social support and cultural match is more nuanced. Studies have shown that whether social support matches independent or interdependent cultural contexts depends on the specific type of social support in question. The types of social support that fit culturally prescribed tasks and goals are likely to be associated with beneficial outcomes, whereas those that violate or threaten cultural values and norms may even have harmful effects. Work on social support seeking has provided evidence for this cultural match idea. Compared to Asians, European Americans are less concerned that seeking social support burdens the relationship (Taylor et al., 2004), and they show more adaptive psychological and physiological stress responses when instructed to seek social support from close others in order to deal with a stressor (Taylor, Welch, Kim, & Sherman, 2007). On the other hand, receiving *unsolicited* social support was more beneficial in reducing psychological distress than was actively soliciting social support among Asian Americans, perhaps because unsolicited help affirms the interdependent aspect of the self by highlighting how much others care about the self (Mojaverian & Kim, 2013; Kim & Lawrie, [Chapter 10](#), this volume). Furthermore, given relational concerns associated with receiving social support in interdependent cultural

contexts, specific conditions may need to be met in order for social support to be associated with better outcomes; high stress likely justifies receiving social support, and low neuroticism probably reduces sensitivity to the relational concerns in such cultural contexts. In fact, received social support was associated with fewer chronic health problems only among Japanese who reported a high level of stress and scored low on neuroticism (Park et al., 2013a).

Feeling the type of emotions that are relevant to culturally prescribed goals has also been shown to predict better functioning. Feeling emotions that confirm one's positive internal attributes (e.g., pride and a feeling of superiority) is more strongly associated with general positive emotions among Americans than it is among Japanese; in contrast, feeling emotions that affirm that one is embedded in relationships and connected to desirable others (e.g., friendly feelings and respect) is more strongly associated with general positive emotions among Japanese than among Americans (Kitayama, Mesquita, & Karasawa, 2006). Also, feeling emotions in a way that fits the average emotional profiles in one's society is associated with better interpersonal functioning across cultures (De Leersnyder, Mesquita, Kim, Eom, & Choi, 2014; Mesquita, De Leersnyder, & Jasini, [Chapter 19](#), this volume).

Engaging in culturally prescribed goals may not only feel good (or not as bad) but may also propel one to engage in certain healthy behaviors. In fact, a recent study based on MIDUS and MIDJA has shown that engagement in culturally prescribed tasks predicts healthy eating (Levine et al., 2016). In the United States, those who score higher on an independent scale tend to engage in healthier eating (e.g., less sugared beverages and more vegetables and fruits), whereas in Japan, those who score higher on an interdependent scale tend to engage in healthier eating. Similarly, the sense of personal control was more predictive of consumption of unhealthy snacks and sweet foods among Dutch participants, but situational triggers were more predictive of this type of consumption among Japanese participants (Ohtomo, Hirose, & Midden, 2011). Furthermore, individuals are more likely to adhere to a physician's recommendation when the physician's emotional style matches the individuals' ideal emotions (Sims & Tsai, 2015). Because health behaviors are important determinants of health, such findings shed light on the pathways through which the pursuit of culturally

prescribed tasks may lead to health. In fact, using MIDUS and MIDJA survey data, Kitayama et al. (2010) found that tendencies toward personal control predict better health in the United States than they do in Japan, whereas low relationship strains predict better health in Japan than in the United States. Also, believing that close others can influence and control things on their behalf predicted better pregnancy outcomes for Japanese mothers than for American mothers (Morling, Kitayama, & Miyamoto, 2003).

The fact that pursuing culturally important goals is linked to better functioning indicates that individuals who are actively engaging in meaningful goal pursuit—a central component of eudaimonic well-being (Ryff & Singer, 1998; Waterman, 2007)—may have better functioning and be healthier across cultures. In line with this prediction, purpose in life, which has been repeatedly linked to better health in Western cultures (E. Kim, Sun, Park, Kubzansky, & Peterson, 2013; Boehm & Kubzansky, 2012), has also been linked to health in Japan; in a recent study based on the MIDJA survey data, Boylan, Tsenkova, Miyamoto, and Ryff (2017) found that having a higher purpose in life predicted a healthier (lower) blood sugar level; in a study focusing on male workers at a Japanese technology firm, Kitayama, Akutsu, Uchida, and Cole (2016) found that meaning in life negatively predicted a threat-related pattern of gene expression involved in inflammation. Also, Japanese who reported having *ikigai* (a Japanese concept that means the sense of a life worth living) showed decreased risks of mortality (Sone et al., 2008). These studies indicate that the feeling that life has worth and is meaningful is associated with better functioning across cultures, though cultural contexts may shape what gives life worth and makes it meaningful.

Cultural Mismatch

On the flip side, failing to pursue culturally sanctioned goals or pursuing goals that are culturally mismatched is associated with worse functioning. One of the most illustrative examples of cultural mismatch is emotion regulation (Ford & Mauss, 2015). The bulk of studies has shown that suppressing and controlling one's emotions, which goes against the

independent cultural task to freely express oneself, is associated with lower well-being and worse interpersonal functioning and mental health in Western cultures (Aldao, Nolen-Hoeksema, Schweizer, 2010; Gross & John, 2003). If the negative effects of emotional suppression are partly due to cultural mismatch, the negative effects should be less pronounced or absent in an interdependent culture in which expression of one's internal states is not part of the cultural mandate. Supporting this idea, many studies have shown that the links between suppression and ill functioning (e.g., lower well-being, lower interpersonal functioning, and more depressive symptoms) found among Americans are weaker or even absent among Asians (e.g., Butler, Lee & Gross, 2007; Soto, Perez, Kim, Lee, & Minnick, 2011). For example, when anger was provoked in an experimental context, the individual tendency to control emotions was associated with an unhealthy ("threat") pattern of cardiovascular responses among European Americans; in contrast, the individual tendency to control emotions was associated with a healthier ("challenge") pattern of cardiovascular responses among Asian Americans (Mauss & Butler, 2010). Such findings suggest that emotional control and suppression are not only less harmful but may also even be beneficial in interdependent Asian cultures where emotional control may serve its culturally prescribed goal to achieve and maintain social harmony/order (Butler et al., 2007; Matsumoto, Yoo, & Nakagawa, 2008).

This pattern of cultural mismatch is not limited to emotion suppression. Experiencing emotions that are discrepant with emotions that are culturally sanctioned and ideal (i.e., an indication that one is failing at a culturally prescribed task) is associated with negative psychological functioning across cultures; for European Americans, larger discrepancies between actual and ideal HAP emotions predicted more depressive symptoms, whereas for Chinese, larger discrepancies between actual and ideal LAP emotions predicted more depressive symptoms (Tsai et al., 2006; Tsai & Clobert, [Chapter 11](#), this volume). Basing one's self-worth on culturally mismatched tasks has also been shown to hinder well-being (Ogihara & Uchida, 2014). The extent to which people base their self-worth on independent tasks (e.g., academic competence, competition) negatively predicted SWB in Japan but not in the United States. In contrast, the extent to which people base their self-worth on interdependent domains (e.g., relationship harmony, others' support) negatively predicted SWB in the United States but not in Japan.

Furthermore, the causal link between the cultural mismatch and ill functioning may be bidirectional. Chentsova-Dutton and colleagues (2007), for example, have proposed that depression reduces individuals' motivation and ability to follow cultural norms. Thus, those who have poor psychological and physical functioning may be less able to act and think in a culturally normative way (see the arrows linking the bottom three boxes in [Figure 12.1](#)). Chentsova-Dutton and colleagues showed that depressed individuals exhibit a pattern of emotion regulation that goes against their cultural norm—a culturally mismatched behavior. When watching a sad film, depressed Asians experienced and showed more sadness than did nondepressed Asians, whereas depressed European Americans expressed and showed less sadness than did nondepressed European Americans. In addition, Norasakkunkit and Uchida (2011) found that Japanese youth who have a high risk for becoming marginalized in society (i.e., Not engaged in Employment, Education, or Training [NEET]) tend to show less endorsement of interdependent values than do low-risk Japanese and also a pattern of motivation that deviates from interdependent cultural norms. Although the direction of causality is not evident (as in other studies based on correlational data), it seems plausible that culturally mismatched patterns of behavior may not only lead to but also arise from psychological and social ill functioning.

Cultural Moderation of the Emotion–Health Link: Buffering and Amplifying Effects of Culture

In Western cultures, positive emotions have been associated with better psychosocial functioning and health (Lyubomirsky, King, & Diener, 2005; Pressman & Cohen, 2005), whereas negative emotions have been linked to worse psychological and physical health (Kiecolt-Glaser, McGuire, Robles, & Glaser, 2002; Watson, 1988). At the same time, how individuals appraise and respond to emotions and emotional events has been shown to influence the psychological and physical consequences of emotions, and certain strategies have been demonstrated to lead to better outcomes than have others (e.g., Gross, 1998; Lazarus & Folkman, 1984; Tomaka, Blascovich, Kelsey, & Leitten, 1993; Watkins, 2008). For example, individuals who were instructed

to appraise their reactions to a stressful task as functional showed more adaptive psychological and physiological reactions than did those who were not given such instructions (Jamieson, Nock, & Mendes, 2012). Also, individuals who were led to believe that it is socially acceptable to feel negative emotions experienced less psychological distress after recalling a personally negative event than did individuals who were not given such beliefs (Bastian et al., 2012).

Therefore, it is possible that in cultures in which adaptive ways to appraise and respond to negative emotions are emphasized and employed, the potential aversive effects of negative emotions are *buffered*; on the other hand, in cultures where adaptive ways to appraise and respond to positive emotions are highlighted and utilized, the potential beneficial effects of positive emotions may be *amplified*. Specifically, compared to individuals in Western cultures, individuals in East Asian cultures tend to have more dialectical views of emotions, to perceive negative emotions as more beneficial and desirable, and to be less avoidant of negative emotions (Miyamoto et al., 2013; Sims et al., 2015). Interestingly, these strategies have been linked to better psychological and physical functioning in both Western (Hayes, Luoma, Bond, Masuda, & Lillis, 2006; Jamieson et al., 2012) and Eastern cultures (Bastian et al., 2012). At the same time, individuals in Western cultures tend to have more nondialectical views of emotions, to perceive positive emotions as more beneficial and desirable, and to savor positive emotions more (Miyamoto & Ma, 2011; Sims et al., 2015). Moreover, these strategies have also been linked to higher well-being, at least in Western cultures (Bryant, Smart, & King, 2005). According to this cultural buffering and amplifying hypothesis, we would expect negative emotions to predict better outcomes in cultures with dialectical beliefs, and positive emotions to predict better outcomes in cultures with nondialectical beliefs.

Supporting this proposition, the links between positive and negative emotions and well-being tend to differ across cultures. Using a representative sample of Japanese and Americans (MIDJA and MIDUS, respectively), Curhan et al. (2014b) found that the inverse association between negative emotions and psychological well-being is stronger in the United States than in Japan. Furthermore, cultural contexts have also been shown to moderate the link between emotions and mental health; positive

emotions are more negatively associated with depressive symptoms among European and Asian Americans than they are among Asian immigrants (Leu, Wang, & Koo, 2011). These findings suggest that negative emotions are associated with less poor psychological functioning in Asian culture, where dialectical views of emotions are dominant, than in Western culture, where such views are less prevalent, whereas positive emotions are associated with better psychological functioning in Western culture, where nondialectical views of emotions are more dominant. A similar pattern has been observed for “rumination”—repetitive reflection on one’s negative feelings and their causes and consequences. In Western cultures, rumination has been associated with negative psychological functioning, especially depression and anxiety (Nolen-Hoeksema, Wisco, & Lyubomirsky, 2008). At the same time, based on a reading of the literature, rumination may not be as strongly associated with negative psychological functioning among Asians as it is among Westerners. In particular, Asians tend more often to take an outsider’s perspective when viewing themselves than do Westerners (D. Cohen, Hoshino-Browne, & Leung, 2007), and research shows that individuals who take a self-distancing perspective (i.e., a perspective in which they recall and visualize a past event from an observer’s perspective as opposed to their own perspective) when reflecting on a negative event tend to experience less negative emotions and reactivity than do those who take a self-immersing perspective (Kross, Ayduk, & Mischel, 2005). Since self-distancing may be an adaptive way to reflect on one’s negative experiences and to buffer the aversive effects of negative emotions, the association between rumination and negative psychological functioning may be weaker among Asian Americans than among European Americans. This is exactly what Chang, Tsai, and Sanna (2010) found. In addition, rumination was associated with less depressive symptoms in Russia than in the United States, and this cultural difference was partly explained by the fact that Russians were more likely than Americans to take a self-distancing perspective (Grossmann & Kross, 2010).

Recently, researchers have started to examine whether culture also moderates the link between emotions and *physical* health. In line with the findings on psychological functioning, recent studies based on MIDUS and MIDJA have shown that negative emotion is a weaker predictor of chronic medical conditions and physical functioning in Japan than in the United

States (Curhan et al., 2014b). Such cultural differences were observed even with biological measures of health, such as inflammation. Inflammation, the body's protective response to tissue damage caused by infection, injuries, or other factors, has been linked to a wide range of health issues, even mortality (e.g., Harris et al., 1999). Dysregulation of inflammatory responses, particularly Interleukin-6 (IL-6), has been suggested to be a central biological pathway through which negative emotions influence physical health (Kiecolt-Glaser et al., 2002). Using biomarker subsamples of MIDUS and MIDJA, Miyamoto and colleagues (2013) showed that among Americans, negative emotions predict an elevated level of IL-6, whereas there is no association between negative emotions and IL-6 among Japanese. The findings remained even after they adjusted for demographic factors, health behaviors, and health conditions, which suggests that cultural differences in the association between negative emotions and inflammation are not attributable to these potential confounds.

Cultural moderation extends to positive emotions. Studies conducted in Western cultures have shown that positive emotions predict cardiovascular risk factors partly by encouraging healthy behaviors and discouraging unhealthy behaviors (Pressman & Cohen, 2005; Boehm & Kubzansky, 2012). Using the biomarker subsamples of MIDUS and MIDJA, Yoo, Miyamoto, Rigotti, and Ryff (2017) recently found that in the United States, positive emotions predict a better lipids profile (a poor lipids profile is a major risk factor for cardiovascular disease). However, this association was weaker or nonexistent in Japan. Furthermore, this cultural moderation of the link between positive emotions and lipids was mediated by body mass index, which is largely shaped by a constellation of health behaviors (as well as genetics). Although future research needs to identify more specific behavioral pathways, these findings imply that positive emotions are associated with healthier behaviors in the United States than in Japan, which result in the cultural moderation of the link between positive emotions and cardiovascular health.

Cultural contexts have also been shown to influence the meaning and health correlates of *expressing* negative emotions, particularly anger. Although expression of anger serves at least two functions (i.e., venting frustration and displaying authority) across cultures, the former function has been shown to be the primary function of anger expression in the

United States, whereas the latter has been proposed to be the primary function in Japan (Park et al., 2013b). Such divergent functions and meanings of anger expression have also been shown to manifest in biological health using the biomarker subsamples of MIDUS and MIDJA (Kitayama et al., 2015; Kitayama, Varnum, & Salvador [Chapter 3](#), this volume). In the United States, where the primary function of anger expression is to vent the frustration experienced in one's life, anger expression positively predicted biological health risks (i.e., inflammation and cardiovascular malfunction), likely because anger expression indexes frustrating personal experiences. In contrast, in Japan, where the primary function of anger expression is to display one's authority, anger expression *negatively* predicted biological health risks, arguably, because anger expression indexes one's social privileges.

In contrast to findings that indicate cultural moderation of the emotion–health link, in a large, international Gallup survey of 142 nations, Pressman, Gallagher, and Lopez (2013) found no difference in the associations between positive and negative emotions and self-reported physical health in nations where positive emotions are more valued (e.g., the United States) and less valued (e.g., Japan). Seemingly contradictory findings may be partly due to the difference in the way physical health was measured. Subjective ratings were used as a measure of physical health in Pressman et al. The association between emotions and self-reported health has been found to be due partly to shared temperament components that underlie both of those measures (Watson & Pennebaker, 1989); that is, individuals who tend to report experiencing more (less) positive emotions also tend to report having better (worse) health, not necessarily because they are objectively (less) healthier, but because their positivity (negativity) colors their *perception* of health. In contrast, more objective measures of health may be less susceptible to such effects of positivity–negativity on the measurement of health.

Mechanisms of Cultural Match–Mismatch

The findings reviewed so far suggest that, in general, the match between one's psychological processes and cultural imperatives is conducive to optimal functioning. Culturally matched ways of thinking and feeling have

been theorized to lead to better psychological and physical functioning, because cultural environments provide individuals with both psychological and social tools and resources (Yoo & Miyamoto, 2018), and because they reward, support, and reinforce those ways of being. Below we lay out three psychological mechanisms and one social mechanism that could provide reasons why culturally congruent ways of being are adaptive.

First, pursuing culturally prescribed ways to live has been proposed to make one feel agentic (Markus & Kitayama, 2003; Miller, 2003). Such a sense of agency has been suggested to be one of the major facets of optimal functioning (Ryan & Deci, 2001; Ryff, 1989). In addition, because the meaning and significance of culturally prescribed tasks are highlighted and readily available in cultural contexts, engagement in ways of thinking and behaving that serve culturally prescribed tasks may make it easier for individuals to find meaning and purpose in activities, and finding meaning and purpose has been proposed to be a central component of functioning well (Ryff & Singer, 1998; Waterman, 2007). Thus, following culturally matched ways of being may lead to optimal functioning through an increased sense of agency, meaning, and purpose of life.

Second, ways of thinking and feeling that are congruent with cultural norms and values should be well-practiced through both lifelong socialization practices and daily cultural practices; therefore, they may become “mental habits” that can be carried out naturally and efficiently. On the other hand, engaging in ways of thinking and feeling that are incongruent with cultural norms and values should require more effort and energy, as they are not typical habits. The additional effort and energy it takes to perform unpracticed tasks may be depleting, which could lead to worse short-term functioning, at least until individuals become efficient at performing culturally mismatched tasks. For example, part of the reason why emotion suppression is less predictive of poor functioning among Asians than among Americans (e.g., Butler et al., 2007) may be due to the fact that Asians are more efficient in suppressing their emotions (Murata, Moser, & Kitayama, 2013), since they have been practicing it more regularly.

A third possible psychological mechanism may take a more indirect route; culture may provide individuals with adaptive tools to appraise and manage culturally matched ways of thinking and feeling. Specifically, culture may provide appraisals and strategies to *buffer* potential negative harmful

effects or *amplify* potential beneficial effects of culturally congruent ways of thinking and feeling. Dialectical ways to appraise negative emotions (Miyamoto et al., 2013) may be an example of a cultural strategy that buffers potentially harmful effects of negative emotions (Curhan et al., 2014b; Miyamoto et al., 2013).

There may also be a social mechanism through which culturally congruent ways of thinking and feeling may be reinforced. The ways of thinking and feeling that match cultural values and beliefs should be more likely to receive social rewards (e.g., increased liking; Na, Choi, & Sul, 2013), whereas ways of being that do not match or that violate cultural values and beliefs may be more likely to receive social disapproval (e.g., Butler et al., 2007) and may even be punished (e.g., Miller & Bersoff, 1992). In fact, Suh (2002) found that individuals who view themselves to be consistent across situations (i.e., a way of being that is congruent with independent cultural values) were judged by their close others to be more socially skilled and likable in the United States but not in Korea. Such social rewards and punishment may in turn lead to better or worse psychological and physical functioning.

Potential Negative Consequences of Cultural Match

Although studies on cultural match show that engaging in ways of thinking and feeling that are congruent with cultural values and beliefs are adaptive, there are certainly cases when culturally congruent ways of being may lead to negative consequences. There are at least two situations in which a cultural match may be maladaptive. One is when a certain way of thinking or behaving that serves a culturally prescribed task also has a negative side effect that is maladaptive for psychological or physical functioning. For example, Oyserman et al. (2007) found that members of racial/ethnic minority groups in the United States perceive healthy behaviors (e.g., exercising, eating healthy food) to be characteristic of European American middle-class people and not typical of their own ingroup. Thus, not engaging in healthy behaviors is likely to help minority members feel included in their own ingroup, even though it may have negative effects on their health (for similar negative effects on academic attainment, see

Oyserman, Bybee, & Terry, 2006). Another example is how pressure from mothers influences their children in interdependent cultures. Reflecting interdependent cultural norms, Asian Americans felt that they were more interdependent with their mothers than did European Americans, and they were more motivated by their mothers' pressure than were European Americans, especially when their mothers worked interdependently with them on a task (Fu & Markus, 2014). At the same time, high parental control predicted worse SWB in both Chinese and American children (Wang, Pomerantz, & Chen, 2007). Although parental control and pressure from mothers are different constructs, these findings point to the potential negative side effects of pressure from mothers, especially when the mothers' pressure is conveyed without interdependence.

Another potential situation in which culturally congruent ways of being can lead to maladaptive functioning is when they are exercised at abnormally high levels. For example, being too "independent" may be problematic, even in independent cultures. In fact, narcissism (which can be considered as the extreme end of independence; Hui & Triandis, 1986) is associated with poor functioning, even in Western culture (Twenge & Campbell, 2009). Also, although pursuing happiness is considered to be an important cultural imperative in Western cultures, actively pursuing happiness too much can lead to poorer psychological and social functioning (Mauss et al., 2012; Mauss, Tamir, Anderson, & Savino, 2011), at least in American culture, where happiness is less likely to be pursued in a socially engaging way (Ford et al., 2015). On the other hand, extreme forms of "interdependence" may also potentially lead to negative outcomes, even in interdependent cultures. Although working hard to fulfill one's duty and obligation is an important cultural value in interdependent cultures, doing so by sacrificing the self too much can have serious negative consequences; in fact, *karoshi*, or "death from overwork," has been a societal issue in Japan (Iwasaki, Takahashi, & Nakata, 2006).

CULTURAL APPROACHES TO STUDYING SOCIAL HIERARCHY AND OPTIMAL FUNCTIONING

So far, we have examined how cultures, such as Eastern and Western, influence the meaning and manifestation of optimal functioning. At the same time, various studies have shown that the social hierarchy that exists within a culture strongly predicts psychosocial and physical functioning. For example, compared to higher status individuals (e.g., those from a higher social/educational class or those with higher socioeconomic status [SES]), lower status individuals tend to have poorer psychological functioning (e.g., self-efficacy; Gallow & Matthews, 2003) and poorer physical health, including mortality (Adler et al., 1994). Cultural-psychological approaches have proposed that culture plays an important role in the link between hierarchy and optimal functioning in two ways. First, different social classes are characterized by different cultural meaning systems. Second, larger cultural contexts in which hierarchies are located can influence their manifestation. These different meanings and manifestations associated with hierarchy both within and between cultures can lead to differences in the way hierarchy is associated with well-being and health.

Social Class and Cultural Mismatch within the United States

Studies conducted within the United States have illustrated that whereas middle-class contexts may be considered to be relatively independent cultural contexts in which uniqueness and self-realization are highlighted and valued, working-class contexts may be characterized as relatively interdependent cultural contexts in which self-adjustment and attention to others are highlighted and valued (Kraus, Piff, Mendoza-Denton, Rheinschmidt, & Keltner, 2012; Stephens, Markus, & Fryberg, 2012). Stephens and her colleagues demonstrated that such social class differences in ideas and values contribute to difficulties experienced by college students from working-class backgrounds. Specifically, college environments tend to emphasize and foster independent cultural values and norms (e.g., being independently motivated, paving one's own innovative pathway), whereas students from a working-class background are more likely than those coming from a middle-class background to have interdependent motivations to attend college (e.g., to help their families, to be a role model

for people in their community), thus creating cultural mismatch (Stephens, Fryberg, Markus, Johnson, & Covarrubias, 2012). When such a cultural mismatch was highlighted by emphasizing the independent norms of university culture, students from a working-class background showed greater psychological distress and greater increases in cortisol while performing an academic task compared to students from a middle-class background (Stephens, Townsend, Markus, & Phillips, 2012). However, this gap disappeared when the university culture was framed as interdependent, thus increasing cultural match for students from working-class backgrounds. These findings suggest that mismatched (matched) cultural values lead to worse (better) psychological and physical functioning even with the United States.

Cultural Moderation of Hierarchy

Although hierarchy is a fundamental way in which relationships are organized across cultures (Fiske et al., 1998), the meaning and manifestation of hierarchy can depend on larger cultural contexts in which the hierarchy is located. For example, with MIDUS and MIDJA surveys, Miyamoto and colleagues (in press) found both similarities and differences in the correlates of SES across cultures. Higher SES is associated with more engagement in self-oriented tasks (e.g., goal striving and self-esteem) in both Japan and the United States, potentially because high SES is associated with more resources and freedom that allow pursuit of such tasks than is low SES across cultures (see Kraus, Callahan, & Ondish, [Chapter 27](#), and Markus & Hamedani, [Chapter 1](#), this volume). However, in Japan, higher SES is also more strongly associated with engagement in other-oriented tasks (e.g., sympathy, social support given to others) than it is in the United State, which suggests that psychological manifestations of hierarchy can also differ across cultures. Such cultural differences in meanings and ideas associated with hierarchy may lead to differences in the way hierarchy is associated with optimal functioning. There are at least three ways in which culture may play a role in the link between hierarchy and optimal functioning.

First, culture moderates what aspect of hierarchy matters for optimal functioning. Hierarchy consists of not only one's objective social status, such

as educational attainment and income, but also one's subjective social status (SSS), that is, how people perceive and judge their own social status. Previous cross-cultural studies have suggested that in independent cultural contexts, people tend to take a more subjective, internal, insider's perspective on themselves, whereas in interdependent culture, people are more likely to take more objective, external, outsider's perspective on themselves (D. Cohen et al., 2007), which presumably helps them to take others' perspectives into consideration and adjust their behavior accordingly. Reflecting such cultural differences in attention to subjective versus objective aspects of the self, the subjective aspect of hierarchy may matter more for functioning in independent cultural contexts, whereas the objective aspect of hierarchy may matter more for functioning in interdependent cultural contexts. In fact, SSS was more strongly correlated with psychological well-being in the United States than it was in Japan, whereas objective social status (i.e., educational attainment) was more strongly correlated with psychological well-being in Japan than it was in the United States (Curhan et al., 2014a).

Second, culture may influence the pathway through which hierarchy influences optimal functioning, especially health. Using MIDUS and MIDJA surveys, Kan et al. (2014) examined which psychological resources mediate the link between hierarchy (including both SSS and objective social status) and objective health (i.e., number of chronic conditions). Consistent with studies that show a stronger role of self-esteem in positive functioning in Western than in Eastern cultures (e.g., Kwan et al., 1997; Uchida et al., 2008), they found that self-esteem mediated the association between hierarchy and objective health in the United States but not in Japan, because self-esteem did not predict objective health in Japan.

Third, culture may also moderate the extent to which hierarchy matters for optimal functioning. In fact, various population-based surveys have shown that the links between SES and psychological and physical functioning (e.g., depressive symptoms, morality, morbidity, and health behaviors) tend to be weaker in East Asian cultures, such as Japan, than in Western cultures, especially the United States (e.g., Inaba et al., 2005; Kagamimori, Gaina, & Nasermoaddeli, 2009; S. Kim, Symons, & Popkin, 2004). There are a variety of potential reasons for such cultural differences in the SES–health link. Social structural differences, such as the lack of

universal health care and the larger degree of stratification in the United States compared to Japan, are likely playing a key role in the stronger SES–health link in the United States. At the same time, it is also possible that psychosocial factors associated with hierarchy are playing a role. For example, the fact that higher SES individuals in Japan need to engage in both self-oriented and other-oriented tasks (Miyamoto et al., in press) may impose greater psychological and physical burden on them.

FUTURE DIRECTIONS

Having covered cultural differences in conceptualization and manifestation of optimal functioning and the role of social hierarchy, we would now like to discuss important directions for the future research. First, cross-cultural investigations of optimal functioning, especially physical functioning, have just begun. In fact, most of the findings are based on East–West comparisons of physical health, especially comparisons involving Japan and the United States. Future studies need to expand these findings to other cultures that exist both between and within nations. Indeed, even within the United States, different ethnic groups hold different beliefs about health (Landrine & Klonoff, 1992), which likely influence their physical functioning. Second, the causal relationship between culturally congruent ways of being and optional functioning needs to be identified. Many of the studies reviewed in this chapter are based on correlational data. The causal direction is likely to be bidirectional; that is, ways of being that fit cultural norms and beliefs should foster psychological and physical well-being, and those who have high psychological and physical well-being may also be able and be motivated to act and to think in a culturally normative way (see bottom three boxes in [Figure 12.1](#)). Future studies need to conduct experiments or longitudinal surveys to illuminate the bidirectionality of these processes. Third, cultural-psychological studies should inform interventions that promote well-being and health in a way that fits with cultural meaning systems. In fact, there is some initial attempt to design and test interventions across different cultural contexts. Below, we outline three potential ways to study interventions from a cultural-psychological approach.

First, it is important to identify whether interventions that have been developed and established in Western culture are effective in other cultural contexts. If certain interventions are incongruent with interdependent cultural values and beliefs, they may not work in interdependent cultural contexts. A few researchers have already begun such an investigation. For example, “expressive writing”—putting one’s thoughts and feelings about a past trauma into words—has been shown to have psychological and physical benefits in Western culture (Pennebaker, 1997). However, expressive writing has fewer health benefits among Asian Americans (Knowles, Wearing, & Campos, 2011), who are less likely to discuss sensitive topics, such as grief and failure experiences, with others (e.g., Asai & Barnlund, 1998), than it does among European Americans. Similarly, although expressing gratitude has been shown to be an effective intervention to increase well-being among Americans, Koreans benefited less from the intervention (Layous, Lee, Choi, & Lyubomirsky, 2013). It is likely that gratitude produces not only positive feelings but also negative feelings, such as indebtedness and guilt, among Koreans, who tend to be concerned about negative relational consequences of social support (Taylor et al., 2004).

Second, researchers may develop or employ an intervention that is congruent with interdependent cultural values and norms. One intervention that involves other-oriented behavior has shown a positive effect in an interdependent culture (Otake, Shimai, Tanaka-Matsumi, Otsui, & Fredrickson, 2006; see also Layous et al., 2013). For one week, Otake and colleagues (2006) asked Japanese participants to become aware of and to keep track of their *own* kind behavior toward other people (rather than others’ kind behavior toward them, as in the case of gratitude). They found that at the end of the intervention, members of the kindness group increased their level of SWB more than did those in the control group, who did not receive any intervention. Therefore, it may be that interventions that increase other-oriented behavior can be effective ways to promote well-being in interdependent cultures. Another effective way to develop an intervention to promote health across cultures is to tailor health-promoting messages to be congruent with cultural values and orientations. By examining the effects of health messages about flossing, Uskul, Sherman, and Fitzgibbon (2009) found that participants showed more a positive attitude toward flossing and a higher intention to floss over the following

week when the message was framed to be congruent with their cultural orientation. Specifically, East Asian participants (who are known to be prevention-oriented) were more persuaded when the message emphasized potential loss (e.g., “Not flossing can be the cause of serious tooth pain and sensitivity”) rather than potential gain (e.g., “Flossing allows a healthy-looking mouth and smile, and also greater enjoyment of foods and drinks”), whereas white British participants (who are known to be promotion-oriented) showed the opposite pattern. Such findings suggest that congruence with cultural values and beliefs may increase the effectiveness of other health messages as well.

A third possibility is to develop or adopt an intervention that is assumed to be based on a universally adaptive mechanism. Studies done in Western cultures have identified various strategies to appraise and respond to negative states and events in certain ways (e.g., Hayes et al., 2006; Jamieson et al., 2012; Kross et al., 2005), and some of these strategies may in fact be effective across cultures (albeit with potential cultural differences in the degree of effectiveness). For example, Buddhism teaches its practitioners to accept and not try to control their emotions, which has inspired therapies even in Western cultures (e.g., Hayes et al., 2006). In contrast, Protestantism considers personal control over one’s mental state to be important (A. Cohen & Rozin, 2001; A. Cohen & Neuberg, [Chapter 32](#), this volume) and teaches its practitioners to control and influence their emotions (Wilken & Miyamoto, 2018b). Wilken and Miyamoto showed that in both Buddhists and Protestants, the more individuals reported accepting their emotions, the less depressive symptoms they reported. Thus, regardless of one’s religious background, accepting emotions seems to be a more adaptive strategy to regulate emotions, which suggests that interventions targeting such a strategy are likely to be effective across different religions.

CONCLUSION

In this chapter, we laid out a cultural approach to optimal human functioning by integrating the existing evidence on the cultural groundings of psychological and physical functioning. Emerging literature suggests that cultural contexts shape the meaning of optimal functioning and its

manifestation in divergent ways. First, cultural contexts provide different conceptualizations of well-being and health. Second, cultural contexts influence how optimal functioning is achieved, what predicts optimal functioning, and who is more likely to achieve an optimal state. Third, cultural contexts and social structural factors, such as hierarchy, work together and sometimes interact with each other to shape optimal functioning. This emerging body of research illustrates how sociocultural contexts, psychological processes, and optimal functioning are mutually influencing and supporting each other (Figure 12.1). Cultural-psychological studies have evolved from demonstrating cultural differences in certain processes to identifying underlying mechanisms (Heine & Norenzayan, 2006). A cultural approach to optimal human functioning may provide a new development for cultural-psychological research; that is, the accumulating evidence on cultural differences in psychological processes and their mechanisms allows for a next stage in the field, in which researchers can explore and identify their implications and what it means to have a good life and to function well in different sociocultural contexts. It is our hope and belief that such investigations will contribute both to a theoretical advancement of the field and to the practical insights that cultural psychological research has to offer.

CHAPTER 13

Wisdom and Culture

Igor Grossmann and Franki Y. H. Kung

Wisdom is often considered to be the pinnacle of human development. Though it is universally cherished, it is unclear whether the concept of wisdom can be applied similarly across cultures. We review the emerging research on this topic, exploring extant scholarly definitions, portrayals of wisdom in the world's philosophies, folk beliefs concerning wisdom and its development, and empirical insights evaluating expression of wisdom-related characteristics. There appears to be a large amount of convergence in scholarly and cross-cultural folk concepts, which suggests that wisdom involves certain aspects of pragmatic reasoning, with less clarity concerning emotion regulatory and prosocial aspects of wisdom. Folk beliefs about wisdom vary across cultures in the degree to which they emphasize social components and characterize development of wisdom as an incremental ability (vs. an immutable entity). Cultures also vary in the likelihood of expressing wisdom. We conclude by calling for a culturally grounded understanding of the distribution and function of wisdom-related psychological phenomena.

For millennia, people have discussed wisdom as one of the most cherished human characteristics (Assmann, 1994). Various philosophical traditions have connected wisdom to the notion of a good life (Kekes, 1995), an orientation toward the greater good (Jeste & Vahia, 2008; Sternberg, 1998), and a virtuous life (Dahlsgaard, Peterson, & Seligman, 2005). What is wisdom? This concept can mean many things, similar to the definition of culture applied across various chapters of this handbook. For instance, wisdom can refer to a particular type of culturally situated literary genre described as the “wisdom literature” (e.g., Solomon’s Book of Proverbs or

Confucius's *The Analects*). At the same time, it may also refer to specific practices and ideals—a set of behavioral patterns and individual attitudes through which people commonly define virtuous individuals and actions, as well as strive to employ such actions in their lives.

In this chapter, we start by integrating different perspectives on wisdom and its relationship to culture. To this end, we first review several common definitions of wisdom. We reflect on three major themes of wisdom scholarship in humanities and social sciences: (1) ancient wisdom literature, (2) folk beliefs about wisdom and its development, and (3) expression of wisdom-related psychological characteristics. We also review scholarship corresponding to each theme, combining etic and emic approaches (Berry, 1990; Grossmann & Na, 2014). Within the etic approach, we focus on cross-cultural expression of specific psychological characteristics. Within the emic approach, we reflect on the culture-specific meanings and utility of these characteristics. Throughout the chapter, we build on existing empirical evidence and theoretical insights in cultural psychology.

DEFINING WISDOM

In many cultures, the notion of wisdom concerns the application of knowledge for judgment about various life situations. For instance, in English the word *wisdom* refers to “knowledge that is gained by having many experiences in life; knowledge of what is proper or reasonable; good sense or judgment” (Merriam-Webster, 2016). In traditional Chinese, an equivalent term “智慧” refers not only to knowledge, but also to intelligence, wit, and brightness (Schroeter & Uecker, 2016). And in Russian, the standard thesaurus refers to “мудрость” as the ability to apply one’s knowledge and experience in a way that results in reasonable decisions and actions (Dmitriev, 2003).

Since the onset of empirical study on wisdom, scholars have proposed a distinct set of definitions that was built on historical traditions and contemporary folk theories. Notably, these “explicit theories” may be distinct from the classic and folk characterizations of the construct, mainly because wisdom scholars aimed to define a scholarly standard for wisdom, as a tool for the development of generalizable methods for capturing the

psychological characteristics attributed to this quality. This approach stands in contrast to the frequent emphasis on norms and ideals in folk theories of wisdom (see next section). Reviewing past definitions, Bangen, Meeks, and Jeste (2013) have identified several major components (see [Table 13.1](#)).¹

TABLE 13.1. Contemporary Scholarly Definitions of Wisdom: Common Components

Author(s)	Recognizing uncertainty and change	Perspective taking and integration	Intellectual humility	Benevolence/prosociality	Emotion regulation	Spirituality	Other
1. Kekes (1983)	X						
2. Taranto (1989)	X			X			
3. Baltes & Staudinger (2000)	X	X	X				
4. Achenbaum & Orwoll (1991)	X	X	X	X	X	X	Integrity
5. Denney, Dew, & Kroupa (1995)				X			Specific skills related to business, politics, etc.
6. Ardel (1997)	X			X	X		
7. Hershey & Farrell (1997)		X		X	X	X	Enlightened
8. Wink & Helson (1997)	X	X		X		X	
9. Sternberg (1998)	X			X			
10. Levitt (1999)			X	X			Honesty, efficiency
11. McKee & Barber (1999)	X			X			
12. Olejnik (1999)	X						Biographical perspective
13. Jason et al. (2001)	X	X	X	X	X	X	Reverence for nature
14. Yang (2001)			X	X	X		Modesty/unobtrusiveness
15. Montgomery, Barber, & McKee (2002)				X			Moral principles
16. Perry et al. (2002)	X			X	X	X	Reverence for nature
17. Takahashi & Overton (2002)				X	X		
18. Webster (2003)		X	X		X		
19. Glück et al. (2005)	X	X		X	X		
20. Brown et al. (2006)	X			X	X		
21. Jeste & Vahia (2008)				X	X		
22. Meeks & Jeste (2009)	X	X		X	X		
23. Grossmann et al. (2010, 2012b)	X	X	X				
24. Jeste et al. (2010)	X	X	X	X	X		Maturity
<i>N</i> definitions with component	16	10	8	19	13	5	

Note. Modified from Bangen, Meeks, and Jeste (2013). In contrast to Bangen et al., we view “lifespan contextualism” (Baltes & Staudinger, 2000) as closely related to the components of perspective taking and recognition of change (over the lifespan); we view neither Baltes and Staudinger’s (2000) nor Grossmann et al.’s (2010, 2012b) definitions as including prosociality as a component of wisdom.

For instance, the framework of *wise thinking* (Brienza, Kung, Santos, Bobocel, & Grossmann, 2017; Grossmann et al., 2010; Grossmann, Na, Varnum, Kitayama, & Nisbett, 2013; see Grossmann, 2017, for review) has included features such as (1) intellectual humility or recognition of limits of one's own knowledge, (2) appreciation of contexts and perspectives that are broader than the issue at hand, (3) sensitivity to the possibility of change in social relations, and (4) *compromise or integration of different opinions* (see [Figure 13.1](#)). Many of these features can be described as “fox-like,” to use Isaiah Berlin's famous classification (2000). Notably, such fox-like characteristics may be advantageous when one aims to produce accurate forecasts about the development of social and political events (Silver, 2012; Tetlock, 2005).

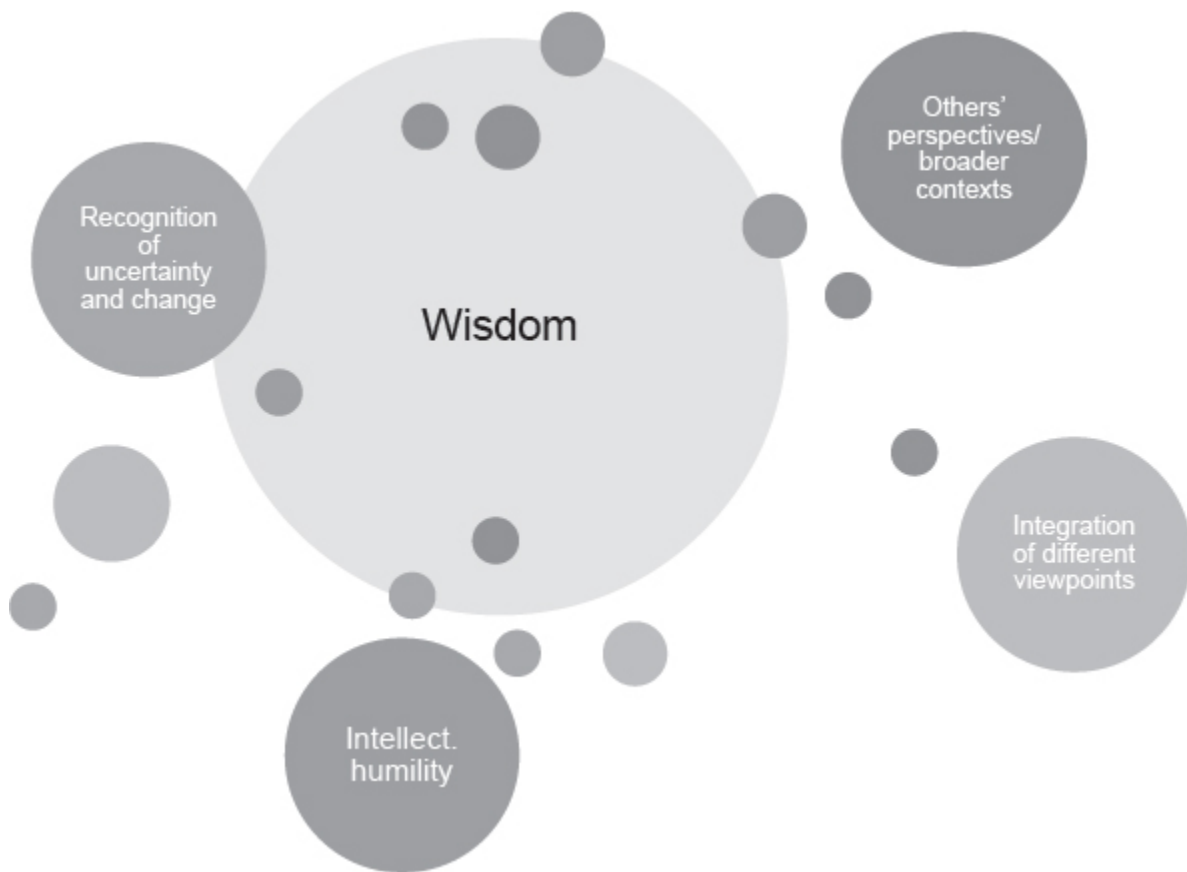

FIGURE 13.1. Aspects of cognitions that are frequently mentioned in contemporary scholarship on wisdom. Adapted from Grossmann (2017).

It is noteworthy that at least one aspect of wisdom-related cognition, the recognition of uncertainty and prospection on change, shares some overlap with the constructs of “naive dialecticism” (Peng & Nisbett, 1999) or “holistic cognition” (Nisbett, Peng, Choi, & Norenzayan, 2001), as discussed in [Chapter 8](#) (this volume) by Masuda, Russell, Li, and Lee. Each construct hinges on facets concerning sensitivity to contextual information. At the same time, cross-cultural studies on naive dialecticism and holistic cognition have largely concerned basic cognitive processing (attention, memory) or general beliefs about change, whereas wisdom scholarship has concerned reflections on concrete, ill-defined interpersonal issues. See Grossmann (2018) for further information about the similarities and differences in the concept of dialectical thinking in philosophy, developmental psychology, and cross-cultural research.

Beyond cognition, it is also evident from [Table 13.1](#) that many scholarly definitions emphasize aspects of self-regulation concerning emotional balance and prosocial orientation. In the latter sections of this chapter, we reflect on the cross-cultural meaning of these constructs and their utility for psychological scholarship on wisdom.

WISDOM AS A CORNERSTONE OF CULTURAL TRADITION

Eminent wisdom scholars Paul Baltes and Ursula Staudinger once stated that “cultural memory is the mother of wisdom” (Baltes & Staudinger, 2000, p. 123). Indeed, the notion of wisdom is common to some of the oldest written cultural products describing the idealized conduct of life. Using stone, papyrus scrolls, and later paper, over millennia, chief priests, kings, and other moral authorities have recorded their reflections on the optimal conduct of human life in the culture they lived. Historians refer to this genre of literary scholarship as the “wisdom literature,” which is essential for not only literary historians but also cultural psychologists. Studying such cultural products, scholars can gain insight into how cultures have developed, as well as conditions promoting various forms of cultural evolution, including diversification and globalization. Understanding and comparing such artifacts can shed light on the conduct of life in Ancient

Rome or China, in Mongolian steppes and Andean or Scottish Highlands, and compare it to values and norms existing in the world today. Thus, it seems that the notion of wisdom is at the very essence of understanding human culture, including its rules and virtues (Miller, Wice, & Goyal, [Chapter 16](#), this volume), and helping cultural psychologists track down the specific meaning systems in a given world, as well as the way they have changed over time.

To understand how concepts of wisdom incubated in the past, some academics have discussed ancient beliefs in early civilizations and documentations of classic philosophies. This line of historical and philosophical analysis has provided some useful directions and narratives to understand the mutual influences of cultural context and the idea of wisdom (for a more detailed review, see Birren & Svensson, 2005; Robinson, 1990). One of the oldest written documentations of wisdom is believed to come from Mesopotamia (3100 B.C.E.), where Sumerians formed their early communities and wrote reflections and stories related to wisdom about happiness and survival on clay tablets (e.g., Teachings of Shuruppak) (Birren & Svensson, 2005). Other early forms of literary wisdom may be found in ancient Egypt. Egyptians recorded sayings about virtues with the aim to educate people about proper behaviors and the appropriate moral code (e.g., Chester Beatty Papyri, I). Moreover, Hebrew religious texts (e.g., the Old Testament in the Bible) portray God as the only path to wisdom and wisdom as a precious virtue that people should actively pursue.

Western Philosophy

The idea of wisdom has also been central to classic Eastern and Western philosophy. Among various traditions, the biggest influence on the concept of wisdom in Western societies was suggested to be Ancient Greek belief systems that promoted the virtue of logical reasoning and knowledge (Robinson, 1990). Most Greek philosophers shared a common notion that wisdom is about being able to understand the truth and have knowledge of the nature of the world. Socrates (470–399 B.C.E.), and later Plato (428–348 B.C.E.) and Aristotle (384–322 B.C.E.), provided arguably the most influential school of Western philosophies on wisdom.

One common interpretation of Socrates' view is that the world is complex and can hardly be boiled down to a simple logical answer. Therefore, one needs questioning to discover what one does not know and learn more about it (Durant, 1961). It is not easy to be wise; in fact, Socrates emphasized that humans' cognitive limitation is a key constraint to wisdom. He suggested that men lie in the spectrum from the ignorant to the wise; because no one, except God(s), has perfect reasoning, no one can be truly wise. Rather, people can become "lovers of wisdom" or sophists (teacher of philosophy) and keep learning (Adler, 1952). Probing the depths of one's own and others' knowledge, the lovers of wisdom can embark on the path to wisdom (as knowledge) by starting to question the world around them.

One of the key proposition attributed to Socrates dealt with the notion of intellectual or epistemic humility. According to Plato, the oracle of Delphi pronounced Socrates the wisest of men, which took Socrates by surprise, motivating him to try find someone wiser than himself among politicians, poets, and craftsmen. Yet, upon discussing various matters with each, he realized that they either lacked knowledge or their knowledge was specific to a narrow domain (for craftsmen). After one such encounter, Socrates is claimed to have said, "So I thought, as opposed to him in this small extent I am wiser: that what I do not know, in no way I think I know" (Plato, 2000, l. 21d, *Apology*). This and some related passages gave Socrates' philosophy of wisdom the name of the "humility theory of wisdom." Having the intellectual humility to understand one's limitation is thought to motivate thinking and questioning, and then the accumulation of knowledge that ultimately made a person wiser. Following the Socratic tradition, Plato's disciple Aristotle is often credited with a further differentiation of wisdom into two components: *sophia* (σοφία)—the theoretical knowledge about the universal truth or true nature of things, and *phronesis* (φρόνησις)—the practical application of knowledge through reasoning about best actions in a given context, with an aim of living well (Aristotle, 1953, Book 6).

As Assmann (1994) pointed out, there is lots of similarity in the main ideas about the conduct of a virtuous life across Abrahamic traditions. Christianity, in particular, exerted a dominant influence on both religious and cultural systems in the West. In line with Socrates' humility theory of wisdom, Christian traditions since the Old Testament (and especially in the New Testament), have proclaimed that humility is associated with wisdom.

This is not surprising given that medieval Christian scholars at least since Aquinas incorporated Aristotelian ideas into their ethics scholarship. In Christians' view, whereas humans are sinners and hence limited in comprehending the ultimate truth, God is perfect and can hold the ultimate truth. Therefore, the path to wisdom is seeking and being humble before God. Because of the divine nature of wisdom, it is common to observe people speaking of wisdom as in part supernatural and related to moral perfections, ideals, and self-transcendence (Birren & Svensson, 2005).

Overall, Western traditions of philosophy highlight knowledge about universal truths, as well as the cognitive ingredients of wisdom (e.g., practical reasoning). In the next section, we explore cultural similarities and differences in the ideas of wisdom from non-Western societies.

Non-Western Philosophy

Non-Western traditions from the Near East, South Asia, and East Asia also include cognitive components when characterizing wisdom, but the concept of wisdom as a whole is less coherent, more dynamic and diverse (Ferrari et al., 2016; Jeste & Vahia, 2008; Khan, 2013; Takahashi & Overton, 2002). Take India as an example. Back in the fourth and third millennia B.C.E., an ancient civilization in India, called Mohejo-daro, left what is believed to be the most ancient Hindu scriptures called *Vedas* (Durant, 1935), which means both "wisdom" and "knowledge." They contained philosophy, hymns, and guidance for ritual scarification, and placed a strong focus on nature. Unlike many other written scriptures that were based on recollection of events and experiences of particular saints or sages, the *Vedas* are an anonymous collection of knowledge. They are believed to be direct revelations from sages, through intense meditation (Scharfe, 2002). The emphasis on unbiased knowing (of the truth) is similar to Western ideas of wisdom. In fact, the word *Vedas* came from the root *vid*, which means to know and understand. However, unlike the Socratic traditions that knowing comes from proactive reasoning, the Vedic traditions emphasized a "more intuitive, personal experience," which does not necessarily involve logical questioning (Takahashi & Overton, 2002).

Later in India, another socioreligious belief system that emerged has exerted immense influence on local and neighboring cultures—Buddhism. There are many streams of Buddhism, yet many of them highlight the search for higher truth through enlightenment (Dyer, 2009), which is achieved not through worship and ritual, but through conduct (Birren & Svensson, 2005). A wise person would act wisely, observing the context, listening to advice, having the knowledge to decide what is reasonable. The initial teachings of Buddhism mostly come from conversations, lectures, and stories taught by Buddha (Birren & Svensson, 2005).

Besides India, China has been another cradle of humanistic and nontheological philosophies of wisdom. From *Tao-Te Ching*, or *The Book of the Way*, Lao-Tzu taught that noninterference in the natural courses of things is the basis of wisdom (Durant, 1935). “To be wise is to realize one’s harmony with nature and to live in conjunction with nature’s rhythm,” Lao-Tzu once said (Bierly, Kessler, & Christensen, 2013, p. 605). Like Western philosophical conceptions of wisdom, Taoism placed high values on knowing via self-reflection. In addition, Lao-Tzu emphasized the value of inaction and unobtrusiveness. For example, such inaction may be valuable in interpersonal conflict scenarios, in which the optimal solution often relies on not engaging and letting matters naturally unfold. Interestingly, in Taoist beliefs, not to engage in conflict resolution is not necessarily an act of indifference, but an act of acceptance and compassion.

Similar to Taoism’s humanistic notion of wisdom, Confucian ideas of wisdom have focused heavily on insights about humans and how to promote virtues (Fischer, 2015), including benevolence or *ren* (仁). In *The Analects*, one of the most widely known books in East Asia, Confucius described *ren* to be natural, something people are born with; however, *ren* can be inhibited by environmental factors. Therefore, Confucianism promotes moral cultivation, or practicing benevolence, as a way to sustain and build people’s *ren* (Li, 2003). Through practicing, wise people can extend their love from close relationships, such as parent–child relationships, to broader social relationships, such as those with leaders and the nation. More generally, Confucius is claimed to have suggested that wisdom is acquired through listening to others and following the good of what one hears (Confucius, 2001, v. VII, 27).

In general, similar to the Greek concepts of wisdom, non-Western concepts of wisdom in Hinduism, Buddhism, Taoism, or Confucianism highlight knowledge and reasoning. At the same time, they appear to orchestrate other experiential and more socioemotional components into the wisdom concept (Takahashi & Overton, 2002).

FOLK THEORIES OF WISDOM

Up to this point, we have discussed some historical insights into what classic philosophers and religious authorities believed to be wisdom across cultures. These notions guide scholars in understanding how people from different cultures may be similar or different in what they traditionally believe wisdom to be. However, to understand the extent to which these traditional concepts are maintained or have evolved in current societies (Varnum & Grossmann, 2017), one needs to examine the contemporary population and assess people's beliefs about wisdom—unpacking what people think wisdom is.

To answer this question, researchers have utilized a wide range of methodologies. Some scholars have focused on descriptor-based ratings of attributes of wisdom, generated by one group of people and rated by another one (Bluck & Glück, 2005), subsequently using multidimensional scaling or factor-analytic techniques to identify common dimensions/factors underlying people's ratings (Clayton & Birren, 1980; Glück & Bluck, 2011; Holliday & Chandler, 1986; Sternberg, 1985). Other scholars have focused on identifying lay exemplars or “prototypes” of wisdom by testing people nominated for their “wisdom” (Orwoll & Perlmutter, 1990; Weststrate, Ferrari, & Ardelt, 2016) or examining what acts from their or others' lives people would describe as wise (Bluck & Glück, 2004; J. Glück, Bluck, Baron, & McAdams, 2005; Oser, Schenker, & Spychiger, 1999). Laypeople's perspectives have been critical in not only informing ideas about scientific theories of wisdom but also helping scientists, psychologists in particular, understand potential cultural and individual differences (Sternberg, 1985).

Empirical Studies in Western Cultures

In one of the first empirical studies on lay beliefs about wisdom, researchers collected a set of wisdom-related words (e.g., *experienced*, *pragmatic*, *empathy*) in a pilot study (Clayton & Birren, 1980). Then they recruited Southern California residents and asked them to rate how similar the words in each unique pair of words were to each other. Using multidimensional scaling, they discovered that laypeople viewed wisdom as a composite that has three main elements: cognitive (e.g., knowledgeable), affective (e.g., empathy), and reflective (e.g., introspective).

In another study on lay beliefs about wisdom in the United States (Sternberg, 1985), 17 adults generated characteristics that they thought a wise person would have. Next, another 30 adults from New Haven, Connecticut, rated these characteristics, allowing the researcher to narrow the list to the top 40. Afterward, 40 undergraduates sorted the characteristics into piles according to similarity between characteristics. Multidimensional scaling revealed three bipolar dimensions: reasoning ability/sagacity, learning from ideas and environment/judgment, expeditious use of information/perspicacity. The results in general supported the idea that wisdom is a multifaceted construct, even though the sample was likely too small to yield robust results from multidimensional scaling analyses. Importantly, laypeople's concepts of wisdom are distinct from intelligence and creativity, and a later study replicated this result using a large sample of North American undergraduate students ($n = 486$; Study 2; Paulhus, Wehr, Harms, & Strasser, 2002). In contrast to intelligence, people associated wisdom with sagacity. People further associated wisdom with reflection and integration of perspectives, whereas they linked creativity with impulsive free-spiritedness. These lay beliefs about wisdom are also in line with current scientific theories and empirical evidence about the relationship between wise judgment and intelligence (Grossmann, 2017; Sternberg, 1998). Though abstract cognitive abilities such as propositional logic (Inhelder & Piaget, 1958) are well suited to master clearly defined problems and are beneficial for good judgment, such abilities are not sufficient for successful navigation of the ill-defined situations that call for wisdom (Clayton & Overton, 1976; Grossmann, 2017). Indeed, wise thinking is only weakly related to measures capturing domain-general cognitive abilities (Grossmann et al., 2010, 2013; Grossmann, Sahdra, & Ciarrochi, 2016d; Staudinger, Lopez, & Baltes, 1997).

More recently, researchers examined the dimensions of wisdom via ratings of wise exemplars and prototypes (Weststrate et al., 2016), presenting 202 participants from Amazon Mechanical Turk (MTurk) a list of wise exemplars generated from a pilot study. Researchers asked participants to provide three or more adjectives to describe the prototypes and rate how similar they are. Using a multidimensional scaling approach, they discovered that people see three major groups of wise exemplars: those who have practical wisdom (i.e., who are pragmatic and strategic, such as Churchill), benevolent wisdom (i.e., who are prosocial and loving, such as Mother Teresa), and philosophical wisdom (i.e., who are intelligent and rational, such as Socrates).

Beyond the United States, researchers in Canada (Holliday & Chandler, 1986) also explored lay beliefs about wisdom, asking 150 individuals to generate a list of 123 descriptions associated with wisdom (e.g., perceptive, experienced). They then invited another 150 Canadians from diverse age groups to rate how characteristic each attribute was of wise people. Using multidimensional analysis, their results suggest that there are five factors for wisdom, including judgment and communication skills, exceptional understanding, general competencies, interpersonal skills, and social unobtrusiveness.

Research on folk theories about wisdom was also conducted in Germany, where Oser et al. (1999) observed that Germans characterize wise acts as (1) paradoxical, unexpected (i.e., acts that are unique from or contrary to most people's choice of actions); (2) moral; (3) selfless; (4) agentic (i.e., acts that overcome internal and external dictates); (5) balancing different interests and trade-offs; (6) implying risk and uncertainty in the situation; and (7) striving toward improving the human condition. These underlying features seem to suggest that wisdom involves certain cognitions, as well as components capturing benevolent/prosocial motives. More directly supporting this notion are results from another study conducted on a large, well-educated sample of Germans (Glück & Bluck, 2011). These results indicate that adult Germans laypeople's views of wisdom include a cognitive component (e.g., knowledge, life experience), as well as a prosocial component (e.g., empathy and benevolence), with both components being central to the definition of wisdom.

Overall, Westerners' lay beliefs about wisdom appear to be distinct from intelligence or creativity (Paulhus et al., 2002; Sternberg, 1985). Moreover, people tend to view wisdom as a multidimensional construct that involves cognitions, prosocial motivations, and balancing of different interests, opinions, and uncertainties (e.g., Oser et al., 1999; Weststrate et al., 2016). Though classic philosophical texts from this region emphasize theoretical knowledge and cognitive processes, it appears that Western contemporary folk beliefs about wisdom concern both cognitions and prosocial orientation.

Extension to Non-Western Cultures and Cross-Cultural Comparisons

Comparing Western and non-Western traditions of wisdom scholarship, some scholars have suggested that there is likely a great deal of similarity in the concepts of wisdom across cultures. For instance, Jeste and Vahia (2008) compared contemporary Western conceptualizations of wisdom with those in the classic Hindu texts of Bhagavad Gita, pointing out such components of Gita wisdom as knowledge of life, self-detachment/contentedness, self-regulation/equanimity, compassion and sacrifice, and integration of these practices for the benefits of one's social environment. Arguably, similar ideas appear in various Abrahamic traditions of the West and the Middle East, as well as in Confucian and Buddhist scholarship. In the Himalayan region of India, Levitt (1999) interviewed 13 Tibetan Buddhist monks to ask what wisdom is to them. Quite similar to the framework of wisdom ideas in the West, the monks described wisdom as involving a cognitive component such as recognizing the truth (i.e., "emptiness"), a reflective component such as transcending the self (i.e., "nonself"), and a socioemotional component that is about understanding suffering and feeling compassion. In Taiwan, Yang (2001; Study 2) surveyed 616 Chinese and discovered that Chinese also viewed wisdom as involving cognitive/analytic (i.e., "competencies and knowledge"), reflective (i.e., "openness and profundity"), and prosocial components (i.e., "benevolence and compassion"). In addition, Yang suggested that "modesty and unobtrusiveness" may potentially be a unique factor in cultures where people emphasize collectivism and social harmony.

It is still unclear whether and to what extent conceptions of wisdom are culturally specific or universal (Curnow, 1999). The major reason is that empirical evidence comparing folk beliefs of wisdom *across cultures* is scarce (Staudinger & Glück, 2011). Most of the scholarship on folk beliefs was either conducted in Western societies or within a single culture. Also, although there are advantages to using descriptors generated by lay people, there are issues with assuring equivalent translation of these descriptors across cultures. One notable exception is the set of studies by Takahashi and Bordia (2000). The researchers recruited 53 U.S. Americans, 50 Australians, 59 Indians, and 55 Japanese to evaluate which personality descriptors most closely match the descriptor *wise*. Their subsequent multidimensional scaling analyses revealed that Indians and Japanese were more likely to cluster *wise* with *discreet*, whereas Americans and Australians were more likely to group *wise* with *knowledgeable* and *experienced*. Takahashi (2013) proposed that these differences are rooted in distinct cultural traditions of the ancient East versus West: Whereas the analytical tradition of the West emphasizes cognitive skills, differentiating them from social skills, this split may be absent in the East. In other words, Japanese and, to some extent, Indians (as compared to Westerners) are more likely to believe that wisdom involves social processes, consistent with corresponding cross-cultural differences in emphasis of collectivistic values and interdependent self-orientation (Markus & Kitayama, 1991).

In our view, such interpretations should be considered with caution. First, empirical evidence for cross-cultural variability is very preliminary, as it comes from a single, underpowered study. Second, without actual measures of values or cultural belief systems, it is possible that any difference observed across samples will be due to sample-specific idiosyncrasies rather than macro-level cultural differences (Grossmann & Na, 2014). Third, other studies indicate that Western conceptions of wisdom include both cognitive/reflective and social processes (e.g., Glück & Bluck, 2011). Therefore, it is possible that the singular observation of cultural differences in emphasis on social (e.g., “discreetness”) versus cognitive aspects (e.g., “knowledge”) of wisdom represents a sample-specific anomaly. More evidence, including evidence from a wider range of cultures, is needed to further our understanding of cultural differences in the beliefs about the core components of wisdom.

FOLK THEORIES ABOUT THE DEVELOPMENT OF WISDOM

In various folk theories and scholarly writings (see [Table 13.1](#)), wisdom is often associated with the notion of maturity. Thus, understanding what people in different cultures believe they can do to develop wisdom is an important question to explore. Notably, before considering specific wisdom-enhancing strategies, it is worth considering whether there are systematic differences in beliefs concerning the malleability of wisdom across cultures in the first place.

A person's beliefs about the malleability of human attributes are highly contingent on culture (Kung, Eibach, & Grossmann, 2016; Su et al., 1999). Individualists (e.g., Americans, Canadians; Markus & Kitayama, 1991) tend to endorse more fixed, or "essentialist," beliefs about the self (Heine & Lehman, 1999). Collectivists (e.g., Chinese, Japanese), on the other hand, stress self-improvement and tend to have more malleable beliefs about the self (Chen, Chiu, & Chan, 2009; Heine et al., 2001; Morling, Kitayama, & Miyamoto, 2002). Consistent with this notion, Grossmann, Kung, Machery, and Stich (2016c) surveyed participants from the United States, Canada, China, and Russia, and found that people from more individualistic cultures (Canada/the United States) held more fixed beliefs about wisdom than did people from more collectivistic cultures (China/Russia) (see [Figure 13.2](#)).

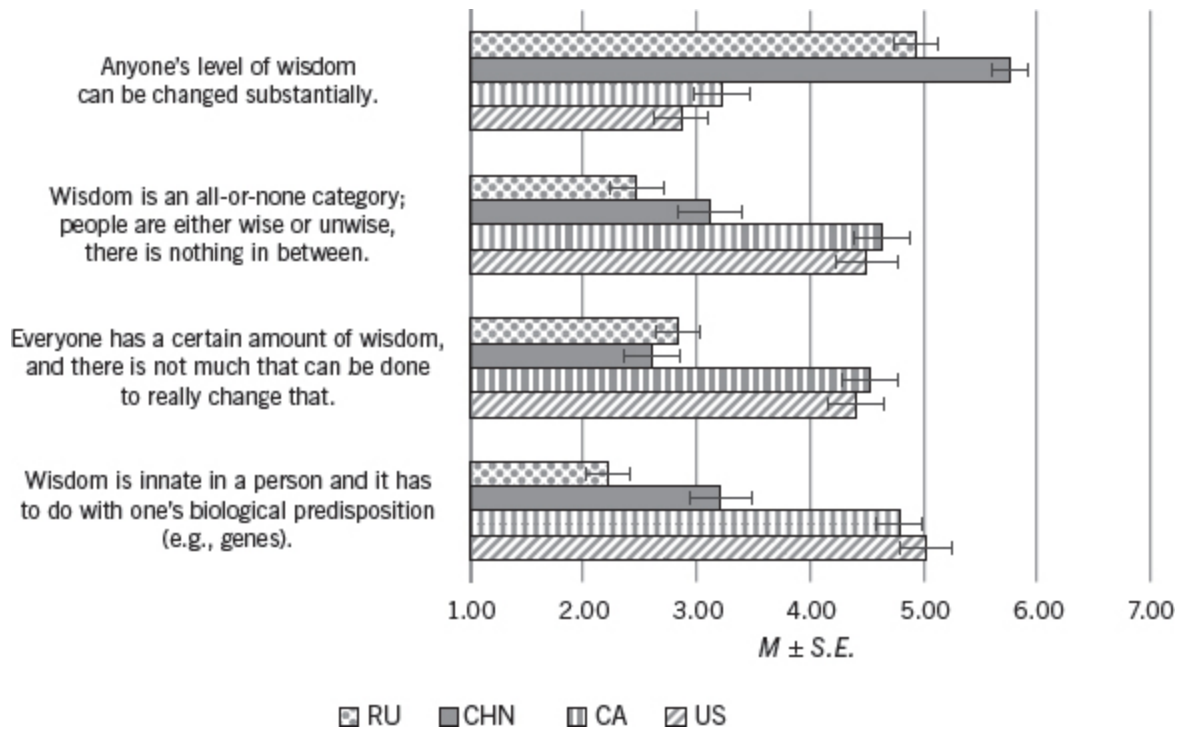

FIGURE 13.2. Malleable versus fixed beliefs about wisdom across cultures (from 1 = *not at all* to 7 = *very much*).

Beliefs about Wisdom-Enhancing Strategies

Grossmann et al. (2016c) asked participants to pick three strategies that in their opinions people in their country would think are the most likely paths to wisdom. The set included 12 strategies capturing experiential (personal and vicarious) factors, the role of contemplation about the world and the self, as well as relational, structural, didactic and naturalistic factors. As [Figure 13.3](#) indicates, participants from all countries emphasized active seeking of new experiences (9.8–15.6%), openness to life events (8.5–21.4%), as well as reflection on the self (6.8–16.7%) and the situation (10.9–15.9%).

FIGURE 13.3. Beliefs about wisdom-enhancing strategies across cultures. Percentages indicate likelihoods of selecting a given strategy as among the top three.

At the same time, [Figure 13.3](#) also reveals some cultural differences. North Americans were more likely to have a focus on firsthand, inner personal experiences (6.7–15%) compared to Chinese (2.3%) and Russians (0.5%), a tendency that was associated with entity beliefs about wisdom. North Americans were also more likely to endorse seeking vicarious experiences through advice from others (12.8–16.7%) than were Chinese (6.2%) and Russians (4.2%). The Russian sample showed a unique pattern in that its members were more likely to focus on strategies concerning openness and reflection than other countries (53.9 vs. 29.2–34.6%). The latter observation is consistent with the stereotype of Russian culture as one endorsing self-reflection and brooding, including reflection on negative experiences (Grossmann & Kross, 2010). Finally, Chinese were more likely than people from the other three countries to endorse cultivation of habits (14.1 vs. 1.9–4.6%) and studying the lives of the sages (16 vs. 2.3–6.4%). It is

possible to trace such beliefs to the teachings of Confucius, which are widely popular in modern China. Confucius explicitly endorsed the cultivation of habits—he once said the “easiest” way to develop wisdom is through imitation of wise people. Indeed, it is common to see this imitation approach in contemporary Chinese learning and education policies; one prominent example is that traditional national examinations in China tested students on the rote memorization of the famous writings of sages. Though playing a less central role, even nowadays biographies and writings of sages are still commonly used as part of the Chinese school curriculum (e.g., moral education) (Ho, 1994; Salili, Chiu, & Hong, 2001).

In summary, it appears that there is a great deal of similarity in how people in different cultures view wisdom. The existing work has so far suggested that wisdom involves cognitive competencies, particularly those concerning reflection on the self, life judgments and decisions, as well as the role of socioemotional skills, including emotion regulation and benevolence. At the same time, we observed a range of culture-specific themes concerning the development of wisdom that are mostly consistent with prior cross-cultural research (fixed vs. malleable view of abilities; the emphasis on deliberate habit cultivation and exemplar-driven teaching in China and the focus on self-reflection in Russia). Before concluding this section, we should point out that the extant work on the concept of wisdom across cultures is still very limited and requires substantial unpacking in future studies. In particular, beliefs about the development of wisdom need further rigorous empirical research.

Beyond Beliefs: How Variable Is the Expression of Wisdom?

The belief that wisdom is malleable, which seems more prevalent in non-Western countries, raises the question of whether the expression of qualities attributed to wisdom are indeed variable within the same person across situations. Moreover, if such qualities are indeed malleable, what are the circumstances promoting wiser judgment? Emerging empirical work has started to explore this question, targeting the cognitive processes involved in a wise judgment (see [Figure 13.1](#)). This work largely supports the non-

Western perspective of wisdom as a malleable construct, showing that people vary dramatically in their likelihood of utilizing wisdom-related cognitions from one situation to the next. In a diary study, Grossmann, Gerlach, and Denissen (2016a) asked a group of adults to fill out a 9-day diary. In the diary, the adults were instructed to reflect on the most significant challenge of the day (e.g., interpersonal conflicts, stressful situations at work, or other daily annoyances). They also answered questions measuring how they reflected on each challenge—whether they recognized limits of their knowledge, considered uncertainty and change in ways the situation might unfold, considered different perspectives on the event, and searched for a compromise between personal and group’s interests (Grossmann et al., 2016a). By plotting the distribution of *between-person* scores—averaging participants’ scores across diary days—and the distribution of *within-person* scores—daily deviations from the individual average scores across all diary days—researchers identified more variability in the degree of wise thinking *within* the same person across different situations (i.e., intraperson variability) than *between* people when averaged across their diary days (i.e., between-person variability) (Mendoza-Denton & Worrell, [Chapter 28](#), this volume). Moreover, participants were more likely to express epistemic humility when reflecting on social situations involving other people as compared to nonsocial situations.

Why are nonsocial situations less likely to evoke wise responses? Experimental evidence suggests that participants’ greater self-focus in nonsocial situations is likely the key. Grossmann and Kross (2014; Huynh, Oakes, Shay, & McGregor, 2017) asked participants to reflect on hypothetical transgressions concerning infidelity and betrayal of trust. Each participant was randomly assigned either to reflect on a transgression concerning a close friend or a transgression concerning him or her personally. Subsequently, participants were asked to describe their thoughts about the future development of the relationship. The result indicated greater wisdom—recognition of limits of their knowledge, consideration of uncertainty and change in ways the relationship might unfold, consideration of different perspectives on the event, and search for a compromise—when reflecting on a friend’s versus a personal transgression. Along similar lines, wisdom potential seems to be heightened when adopting an ego-decentering perspective on a difficult situation (e.g., viewing events from a

“fly on the wall” vantage point; Kross & Ayduk, 2011) compared to adopting an egocentric perspective (e.g., viewing events through a first-person vantage point). In two experiments, Kross and Grossmann (2012) tested how graduating college seniors reflected on their job prospects during the peak of the recent economic recession or how American college students reflected on polarized political issues in the heat of the U.S. Presidential election campaign. In both experiments, participants in the ego-decentering condition showed a greater ability to reason wisely (recognition of the limits of one’s knowledge and recognition of change) compared to participants in the egocentric condition.

It appears that people in different cultures have a potential for expressing wisdom in their lives, particularly if processing information in an *ego-decentered* fashion. Why? From the first-person viewpoint, people draw attention to concrete, focal features of the environment. In contrast, the third-person viewpoint enables people to remain at the level of abstract mental representations, with access to a wide range of meaning structures. Thus, when perceiving an event from the egocentric first-person viewpoint, people are more likely to focus on the concrete, focal features of the experience. In contrast, from the ego-decentered, third-person viewpoint, people are more apt to define that event in relation to its broader context (Kross & Ayduk, 2011; Libby & Eibach, 2011).

EXPRESSION OF WISDOM IN A MULTICULTURAL CONTEXT

Despite common beliefs about the central themes of wisdom, the expression of psychological characteristics attributed to wisdom (see [Table 13.1](#)) can take different forms across cultures. Cultural differences in experiences people accumulate over the lifespan and social learning suggest substantial room for cross-cultural variability in wisdom expression across modern societies; that is, the expression of wisdom-related abilities likely depends on the specifics of the cultural environment, involving certain implicit or explicit cultural practices. In this section, we review emerging cross-cultural research on wisdom-related characteristics.

Wisdom-Related Cognitions across Cultures

A number of studies indicate that cultural groups such as Chinese, Japanese, or Russians tend to be more oriented to the social context when thinking about interpersonal experiences than other cultural groups, such as European Americans, who tend to focus on the individual when reflecting on similar experiences (D. Cohen et al., 2007; Grossmann & Kross, 2010). A greater focus on the social context may help individuals in non-Western countries achieve the overarching goals of relatedness and social connection, which are of higher value among these cultural groups (Hofstede, 1980; Triandis, 1989). If cultures differ in their focus on the social context and interpersonal harmony versus the individual and personal achievement, one may expect parallel differences in wise reasoning about social conflicts. Specifically, people from cultures that encourage a focus on social contexts (e.g., Japan) may show a greater ability to reason wisely than do people from cultures that promote an individual-centered focus (e.g., the United States).

Notably, cultures also differ in the ways they approach social conflicts, providing distinct experiences that individuals collect over the lifespan about how to approach difficult situations. Some cultures, including the Japanese culture, encourages maintenance of interpersonal harmony (Holloway, 1988) and stability in close relationships—themes that are consistent with the Japanese focus on social context (Grossmann & Na, 2014; Varnum, Grossmann, Kitayama, & Nisbett, 2010). For instance, Japanese are more likely to explicitly teach their children how to avoid and reduce conflicts than are Americans (Imada, 2012), because conflicts are viewed as more damaging in the East than in the West (Cho & Park, 1998; Friedman, Chi, & Liu, 2005; Ohbuchi & Atsumi, 2010). Other cultures, including American culture, promote themes consistent with an individual-centered focus (e.g., development of personal preferences and individuation in relationships), which may often prompt interpersonal conflicts (Keller, [Chapter 15](#), this volume; Rothbaum, Pott, Azuma, Miyake, & Weisz, 2000). Consistent with these differences in social orientation, East Asians prefer less direct forms of social conflict management (e.g., avoidance strategies, third-party mediation) to a greater extent than do Americans, who in turn prefer a direct conflict management strategy (Leung, 1988; Morris et al., 1998; Ohbuchi & Takahashi, 1994) more than do Hong Kong Chinese or

Japanese. Cultural differences in conflict management styles suggest that Americans experience more conflict over the lifespan, which provides opportunities to learn better ways to deal with it. It therefore follows that experience-related gains in wisdom may be more pronounced in the West than in the East. In other words, what people in Japan may be learning the “easy” way through social learning, people in the United States may be learning the “hard” way, through personal trial and error.

These ideas were recently tested in a multisession study involving age- and social-class-heterogeneous samples of Americans from the Midwest and Japanese from the Tokyo Metropolitan area (age range: 25–75 years; Grossmann et al., 2012b). Participants read newspaper articles describing a series of intergroup and interpersonal conflicts (Grossmann et al., 2010). An interviewer asked participants to reflect aloud on the future development of the issues described in the article, using such probes as “What do you think will happen next? Why do you think it will happen as you just said? What do you think should be done?” Participants’ responses were transcribed and content-analyzed by independent coders for wise reasoning, using the dimensions from [Figure 13.1](#) (from 0—*no mention of the dimension* to 2—*clear mention of the dimension*). Results indicated that younger and middle-aged Japanese showed greater ability to reason wisely about societal and interpersonal conflicts than did their American counterparts. These results held when researchers controlled for cognitive abilities, occupational prestige, and response length.

Across countries, older participants in this study talked more, often went off on a tangent, showed poorer performance on tests of fluid cognitive abilities and a similar level of crystallized cognitive abilities compared to their younger counterparts, all of which are consistent with a large body of research on aging-related changes in general cognitive abilities and distractibility (e.g., Healey, Campbell, & Hasher, 2008; Schaie, 1994). Despite these limitations, older (compared to younger) Americans showed wiser reasoning about social conflicts, whereas there was no age effect in Japan (see [Figure 13.1](#)). This latter observation is consistent with the idea that Americans acquire wise reasoning abilities in older age in part because potential conflicts are less likely to be preempted early in their lives than they are for Japanese (Ohbuchi & Takahashi, 1994), providing Americans with a greater opportunity to learn about conflict resolution over the

lifespan. At this point, it is not clear how such cross-cultural differences generalize beyond U.S.–Japanese comparisons. Nor is it possible to separate developmental versus cohort effects. Nevertheless, together these results paint a consistent picture that contexts promoting a focus on the self as independent from others inhibit one’s ability to reason wisely.

Wisdom-Related Cognitions across Subcultures

Cultural differences in social orientation are not limited to differences between countries, but can also involve different social groups within a country, for instance when comparing different social classes. Recently, many researchers started to approach social class as a form of culture (e.g., Kraus, Piff, & Keltner, 2011; Grossmann & Huynh, 2013), observing systematic social class differences in the degree to which people are attuned to others. Lower socioeconomic status (SES) is associated with greater likelihood of defining oneself and one’s personal goals through relationships with others (Grossmann & Varnum, 2011; Kraus, Callaghan, & Ondish, [Chapter 27](#), this volume; Stephens, Fryberg, & Markus, 2011; Stephens, Markus, & Phillips, 2014). It is also associated with greater accuracy in discerning others’ emotions and having compassion for them (Kraus, Côté, & Keltner, 2010). Eye-tracking (Dietze & Knowles, 2016) and neuroscience studies (Varnum, Blais, Hampton, & Brewer, 2015) show that persons with low SES are more likely to be vigilant about their social environment. Drawing on these observations, Brienza and Grossmann (2017) hypothesized that lower-class culture would promote wiser reasoning about interpersonal conflict situations. To address this question, researchers surveyed over 2,000 adults from the United States who differed in SES. To assess wise reasoning in an ecologically valid and unbiased fashion, researchers asked participants to reconstruct recent experiences from their lives (Brienza et al., 2017). Subsequently, participants indicated the extent to which they engaged in several aspects of pragmatic reasoning, including (1) recognition of the limits of their knowledge/intellectual humility, (2) recognition of the world in flux and change/consideration of multiple ways a situation might unfold, (3) recognition of others’ perspectives, (4)

consideration of/search for compromise and recognition of the importance of conflict resolution, and (5) application of an outsider's vantage point.

Researchers examined how individual-level indicators of social class were associated with wise reasoning. To this end, Brienza and Grossmann (2017) performed a separate set of multilevel analyses, with participants nested within states, with individual-level social class (a combination of education and income) as a predictor of wise style. Higher individual social class was associated with significantly lower wise reasoning scores. The effect of individual status on pragmatic reasoning was robust when researchers controlled for gender and age, social desirability, and emotional intelligence. Thus, it appears that in spite of higher social class's association with superior performance on intelligence tests (e.g., Bridges & Lillian, 1917; Nisbett, [Chapter 7](#), this volume; Witkin, 1969), higher SES culture reduces the propensity to utilize wise reasoning in interpersonal experiences.

Beyond Cognition: The Meaning and Expression of Wisdom-Related Emotion Regulation and Prosocial Characteristics across Cultures

As reported in [Table 13.1](#), numerous psychological scientists have also characterized wisdom as an ability to successfully regulate their emotions and pursue prosocial goals. However, what does it mean to regulate one's emotions and be prosocial? Research in cultural psychology from the last few decades started to indicate dramatic cross-cultural variability in these constructs (see also Tsai & Clobert, [Chapter 11](#), and Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume).

The Meaning of Emotion Regulation across Cultures

On a broad level, folk and scholarly notions of affective processes linked to wisdom concern the notion of adaptive emotion regulation. Affective scientists and clinical scholars often define emotion regulation as “the processes by which individuals influence which emotions they have, when they have them, and how they experience and express these emotions”

(Gross, 1998, p. 275). What does it mean to successfully regulate one's emotions? To address this question, some clinical psychologists have focused on mental health outcomes of emotion regulation strategies. For instance, based on results of a recent meta-analysis, Aldao, Nolen-Hoeksema, and Schweizer (2010) have suggested that reappraisal (i.e., generating benign or positive interpretations or perspectives on a stressful situation as a way of reducing stress; Gross, 1998) and acceptance (e.g., nonjudgmental acceptance of emotions; Aldao et al., 2010) are adaptive for one's mental health. Furthermore, Aldao and colleagues have classified avoidance (including experiential and behavioral avoidance), rumination (Nolen-Hoeksema, Wisco, & Lyubomirsky, 2008), and suppression (Hayes, Strosahl, & Wilson, 1999) as maladaptive strategies. Based on such analyses, it seems tempting to conclude that reappraisal and acceptance are "wise" strategies, whereas avoidance, rumination, and suppression are "foolish," in that the former set of strategies leads to adaptive outcomes, whereas the latter leads to maladaptive outcomes. However, such conclusion are largely based on data from North American and Western European samples. For instance, the most recent meta-analysis of the structure of emotion regulatory strategies (Naragon-Gainey, McMahon, & Chacko, 2017) included only one study outside of Europe or North American cultures. Are there cross-cultural differences in the preference and utility of emotion regulation strategies?

Emerging work suggests that whereas Easterners are more likely to suppress emotions than are Westerners, East–West differences in emotion regulation occur often in the ends rather than the means. For example, European Americans prefer to maximize their positive emotions and moods, while decreasing negative ones (Miyamoto, Yoo, & Wilken, [Chapter 12](#), this volume; Miyamoto, Ma, & Petermann, 2014). However, they are also likely to encourage feeling and expressing (desired) emotions as a sign of the unique inner features of the self (Kim & Markus, 1999), even if such seeking may diminish their actual affective well-being (Ford et al., 2015). In contrast, people from cultures such as China or Japan are more likely to regulate emotions in the service of interpersonal harmony, through either suppression (Matsumoto, 2006) or reappraisal (e.g., focusing on the positive in negative situations and vice versa; Grossmann, Karasawa, Kan, & Kitayama, 2014; Grossmann, Huynh, & Ellsworth, 2016b; for review, see

Grossmann, 2018; Grossmann & Ellsworth, 2017). Suppression and reappraisal are commonly used in societies with a strong sense of social order and hierarchy, and the two strategies are less likely to be seen as diametrically opposed in such societies (see the 23-country study in Matsumoto, Yoo, & Nakagawa, 2008).

The relationship between emotion regulation strategies and psychological outcomes appears to vary across cultures as well. Cross-cultural studies examining effects of suppression on mental health indicate that suppression is linked to detriments in life satisfaction, higher rates of depression, and negative perceptions by others among Anglo Americans, but not among Hong Kong Chinese (Soto, Perez, Kim, Lee, & Minnick, 2011; Miyamoto et al., [Chapter 12](#), this volume) and Asian Americans (Butler, Lee, & Gross, 2007; Cheung & Park, 2010). Moreover, the study of autonomic reactivity during emotion control after anger provocation indicates a physiological signature of threat among Anglo Americans, but a signature of challenge among Asian Americans (Mauss & Butler, 2010). In other words, Asian Americans find it easier to control their emotions after the anger provocation than do their Anglo American counterparts.

There is also evidence that the negative effect of rumination on mental health is culture-specific. Russians were found to report ruminating more than European Americans (Grossmann & Kross, 2010; Study 1), possibly because Russians are more vigilant about negative information than are Anglo Americans (Grossmann, Ellsworth, & Hong, 2012a). At the same time, greater ruminative tendencies among Russians were not linked to greater depressive symptomatology, even though ruminative tendencies were linked to depressive symptoms among European Americans. Why? In another study (Grossmann & Kross, 2010; Study 2), researchers asked Russians and Anglo Americans to ruminate on a recent interpersonal experience of being angry at another person, then to report on the cognitive strategies adopted when ruminating and their level of postruminative distress. Results indicated that Russians were more likely to adopt a third-person perspective when reflecting on the experience, whereas Anglo Americans were more likely to immerse themselves in their experience. Russians also reported less distress than European Americans, and these differences were in turn statistically accounted for by the different cognitive

strategies Russians and European Americans used when reflecting on their anger-inducing experience.

Meaning of Prosociality across Cultures

Cultures differ in their meaning of prosociality as well. For example, U.S. Americans see being prosocial partly as an expression of the self, and they act prosocially out of respect for the other person. In economic games with a stranger, U.S. American participants were highly cooperative, at the risk of being exploited. They reported that they chose to be cooperative not because they believed their partner was trustworthy, but because they meant to show respect to the partner (e.g., Dunning, Anderson, Schlösser, Ehlebracht, & Fetchenhauer, 2014). East Asians, on the other hand, seem to see prosocial actions as a reasonable strategy only when there is an assurance of reciprocity. Logically, assurance of reciprocity is greater among ingroup members. Indeed, compared to people in Western societies, East Asians tend to express more trust toward their ingroup than toward a stranger (Huff & Kelley, 2003; Yamagishi, 1988; Yamagishi, Jin, & Miller, 1998; cf. Buchan & Croson, 2004; Yuki, Maddux, Brewer, & Takemura, 2005). This preference was not easily explained by ingroup favoritism, but by the expectation that prosociality is more likely reciprocated by an ingroup member than by a stranger (Yamagishi et al., 1998). Increased expectation of reciprocity also explains why knowing an indirect contact (e.g., a common friend) increased East Asians' level of trust toward a stranger, a pattern that was not observed among U.S. Americans (Chua, Morris, & Ingram, 2009; Yuki et al., 2005). This is because an indirect contact can potentially keep the stranger's behavior in check, thus allowing East Asians to have more confidence that the stranger will reciprocate the favor in the future.

On the receiving end of prosociality, some research has shown that expectation of reciprocity also affects when and why people accept others' prosocial gestures. In Chinese, there is a concept called *renqin*, which is a benevolence debt: If people accept a favor, they expect they will need to return one in the future (King, 1989). Empirical studies have found that Chinese, compared to European Canadians, are less likely to accept even a small gift (e.g., a coffee) from acquaintances and would have felt more

uncomfortable if they did (Shen, Wan, & Wyer, 2011). Relatedly, East Asians also seem less comfortable with seeking help, even from close others, because they worry about the burdens they are placing on those others (Kim & Lawrie, [Chapter 10](#), this volume; Kim, Sherman, & Taylor, 2008).

Overall, this work suggests that a fuller understanding of whether and how emotion regulation and prosociality reflect wisdom requires a greater understanding of the culture-specific meaning of each construct. As with wisdom-related cognitions, characterization of emotion regulatory or prosocial strategies as “wise” will likely depend on the understanding of situational demands in a given cultural context (Grossmann, 2017).

CONCLUSION

When the Swedish zoologist Carl Linnaeus devised the binominal nomenclature system of species, he reserved the name *Homo sapiens*—the wise being—to refer to humans. How does the notion of wisdom relate to the concept of culture? In this chapter, we have reflected on several possibilities, drawing from work in philosophy and psychology. Empirical work from these fields starts to suggest a large degree of cross-cultural similarity concerning folk theories about wisdom and its development. At the same time, the niches people live in are diverse and changing, so the concept of wisdom appears to evolve and diverge across cultures as well (Varnum & Grossmann, 2017). Indeed, folk theories about the development of wisdom appear to differ across cultures. So do expressions of wisdom-related cognitions. Evidence concerning the role of emotion regulation and prosociality relative to wisdom is less clear, because of substantial cross-cultural variability in the meaning of each construct. Overall, cultural variations observed in wisdom-related characteristics so far appear to be informed by dominant cultural values endorsed in a given society, calling for a culturally grounded understanding of wisdom-related phenomena.

ACKNOWLEDGMENTS

Work on this chapter was supported by an Insight Grant (No. 435-2014-0685) from the Social Sciences and Humanities Research Council of Canada, the Ontario Ministry of Research, Innovation

and Science (Early Researcher Award No. ER16-12-169), and the Emerging Scholar Mentorship Grant, UW Network on Aging Research to Igor Grossmann. We thank Dov Cohen, Michael Ferrari, and Andreas Fischer for fruitful comments on earlier drafts of this chapter.

NOTE

1. Bangen et al. (2013) have also included the underspecified themes of “knowledge/decision-making” and “self-reflection,” which were omitted from Table 13.1 due to the very broad nature of these terms and insufficient detail. For instance, self-reflection can be adaptive or maladaptive (Grossmann & Kross, 2010), and knowledge can be theoretical or practical (Ardelt, 2004; Baehr, 2012; Baltes & Kunzmann, 2004; Fischer, 2015).

CHAPTER 14

Cultural–Clinical Psychology

**Yulia E. Chentsova-Dutton and Andrew G.
Ryder**

Awareness of cultural diversity has grown increasingly important to clinical psychology, but cultural psychology has not much influenced this development. This is unfortunate, as studies of mental disorder present us with many examples of cultural variation in conceptualization, prevalence, presentation, and course of mental disorders, as well as the beliefs and practices relevant to managing their symptoms. Much of this research would benefit from a cultural approach. We present the cultural–clinical psychology perspective as an attempt to move toward a closer integration, grounded in the premise that mental disorder is an emergent property of culture, mind, and brain. We follow the typical course of a sufferer, starting with the ways in which culturally shaped vulnerability and stress factors affect the emergence and maintenance of a disorder. Then, we turn to the ways in which symptoms, and responses to them, are shaped by cultural scripts of normality and deviance, with an emphasis on dynamic loops that generate symptoms, perpetuate them, and strengthen their associations with one another. Finally, we consider the state of knowledge on clinical evaluation and intervention. Throughout the chapter, we emphasize research that considers the interplay of culture, mind, and brain, and that does so in an effort to better understand and explain the influence of the sufferer’s cultural context.

In recent decades, researchers have grown increasingly convinced that mental disorders are, in many important ways, disorders of the brain. Studies have now catalogued the complex sets of genetic vulnerabilities,

changes in brain structure and activation, and neurochemical and hormonal shifts integral to psychopathology. Research on mental disorders nonetheless continues to benefit from understanding them as disorders of the mind. Clinical psychologists in particular have developed rich research programs that foreground cognitive, affective, behavioral, and interpersonal patterns in order to better understand and treat psychopathology. Rather than placing brain and mind-centered approaches in opposition, some of the most exciting studies in recent years have successfully integrated them (e.g., Hamilton et al., 2011).

Mental disorders are also shaped by the cultural context, at times powerfully. A number of important cultural differences have now been documented, covering different aspects of psychopathology, such as (1) prevalence of mental disorders (e.g., major depression; Ferrari et al., 2013); (2) the type, content, and severity of symptoms (e.g., autism; Chung et al., 2012); (3) course of illness (e.g., schizophrenia; Kulhara & Chakrabarti, 2001); and (4) links with important outcomes (e.g., between mood disorders and suicides; Nock et al., 2008). Yet potential mechanisms to help explain these variations are rarely studied. In many cross-national and interethnic comparisons, group differences are reported, and “culture” is invoked as a catch-all explanation for the findings. Although these studies complement their discussion of differences with post hoc speculations about why culture matters, incorporating these possibilities into the study design is usually left to future research.

This future is overdue. Although hypotheses abound, we still know surprisingly little about the specific cultural meanings and practices that shape patterns of cultural variation in mental disorders. At present, when “cultural competence” is incorporated into clinical psychology, it tends to play the important but limited role of ethical watchdog, flagging a set of additional concerns to be considered by practitioners once they have assimilated the basic research. As clinical psychology increasingly finds its footing as an evidence-based discipline, this role is no longer sufficient. Cultural psychology offers an important set of findings—and even more importantly, a set of approaches—to inform evidence-based clinical research and culturally competent practice. Cultural psychology, in turn, stands to benefit from broadening the range of psychological processes central to our field, not least through consideration of the vital clues about normal

functioning that come from careful study of dysfunction. Moreover, as cultural psychologists seek to expand their traditional concern for culture–mind links to include the brain (Kitayama, Varnum, & Salvador, [Chapter 3](#), this volume), they stand to benefit from a sustained engagement with clinical psychology, a subdiscipline increasingly operating at the mind–brain intersection. We refer to this culture–mind–brain integration, applied to the study of mental disorder, as “cultural–clinical psychology” (Ryder, Ban, & Chentsova-Dutton, 2011).

In describing our vision of cultural–clinical psychology in this chapter, we follow the prototypical pathway followed by a person suffering from a mental disorder. Let us imagine Hana, someone who is at risk for developing symptoms of a mental disorder. Given that no disorder affects everyone, what biological, psychological, and cultural factors make Hana, rather than others, vulnerable? Are they impacted in specific ways by the sociocultural context? What, if anything, is known about the nature, course, and significance of these symptoms in her context? Are they recognized and scripted? As symptoms emerge, what is the relationship between Hana’s physiological changes and her experiences of distress on the one hand, and cultural scripts available to her on the other? Finally, how might she talk about her symptoms, if at all, and how might others in her cultural context understand these symptoms and respond? What diagnostic labels are used? What treatment paths are available? Cultural–clinical psychology is concerned with this broad set of questions in pursuit of two central aims: to understand the cultural shaping of mental disorder, and to apply this understanding to the improvement of clinical evaluation and intervention (Ryder et al., 2011).

MUTUAL CONSTITUTION OF CULTURE, MIND, AND BRAIN

Before following this path, however, let us first briefly pause to consider how we understand the interrelation of culture, mind, and brain. Social science of medicine has for decades made a distinction between biological “disease” (i.e., brain) and subjectively experienced “illness” (i.e., mind) (Boorse, 1975; Eisenberg, 1977; Hofmann, 2002). Twaddle (1973) introduced a third term,

“sickness,” referring to the social identity ascribed to the sufferer (i.e., culture). We find these terms useful to highlight how distress operates at a given level, but generally prefer “disorder” to capture the complex interactions of disease, illness, and sickness across the culture–mind–brain. Our aim here is to acknowledge the central importance of the three domains encompassed by the biopsychosocial model, and also push beyond this model in important ways.

We begin with the core claim of cultural psychology: that culture and mind are mutually constitutive (Shweder, 1991). We cannot reduce culture to mind or vice versa. Individual people are uniquely situated within their cultural contexts, thinking and acting in different ways that are nonetheless culturally meaningful (Sperber & Hirschfield, 2004). At the same time, these contexts do not simply exist as abstract and essentialized human groups, but instead are shaped by the individual minds that comprise them. In keeping with both long-standing ideas in cultural psychology (e.g., the importance of cognitive tools; Vygotsky 1978) and contemporary developments in philosophy of mind, we understand “mind” to be extended to incorporate habitually used “tools”, such as a notepad to supplement memory or a close other to aid emotion regulation (Clark & Chalmers, 1998; Ryder et al., 2011).

Over the past few decades, there has been increased attention to the role of the brain and nervous system, and the ways in which they should be added to the story of mutual constitution (Han & Northoff, 2008; Kitayama et al., [Chapter 3](#), this volume; Kitayama & Uskul, 2011; Ryder et al., 2011). The human brain is adapted specifically for cultural acquisition and responds to cultural inputs with a considerable degree of plasticity (Wexler, 2006). At the same time, plasticity does not mean infinite possibility: rather, it involves important biological constraints. The inclusion of the brain in what we consider ultimately to be a single system moves us away from overly simplistic biological and sociocultural forms of reductionism: The brain both shapes and is shaped by culture and mind. This view of culture–mind–brain as a single system highlights, and bypasses, the difficulties that result from an overly narrow focus on one level. Although clinical psychologists are familiar with the three levels of the “biopsychosocial” approach, there is a tendency not to dwell on the extent to which they interact. We believe treating culture–mind–brain as a single multilevel

system rather than three important-but-separate domains has profound implications: We cannot reduce our explanations to one level, but instead must contend with a system in which a change at one level cascades to the others.

Consider as an example the reported increases in mental health problems among American undergraduates (Kitzrow, 2003; Pledge, Lapan, Heppner, Kivlighan, & Roehlke, 1998). We know that developing children benefit from proximity with adults, with such proximity regulating the brain's responses to threat and offering measureable health benefits (Beckes & Coan, 2011). European American cultural contexts promote autonomy, with positive consequences for well-being (Fischer & Boer, 2011). This cultural emphasis on autonomy is expressed in higher levels of residential mobility in the United States compared to many other societies (Esipova, Puglese, & Ray, 2013); a major autonomy milestone is moving away for college. An older cultural model managed this potential conflict between social proximity and demands for autonomy in college by slowly increasing opportunities for autonomy throughout adolescence. In recent years, however, fueled by perceptions of an unsafe world, American parents have been delaying these milestones (Wyver et al., 2010). Parents now spend increasing amounts of time with children despite perceptions that earlier decades were more "family-focused" (Gauthier, Smeeding, & Furstenburg, 2004). The result is that more students enter college unprepared for the sudden shift in autonomy demands. Although the extent of this shift remains unclear, it is thought to be costly for mental health. Note that there are benefits to both social proximity and autonomy, to both independence in college and to appropriate caution in a genuinely unsafe environment. But in a particular cultural system, during a particular historical period, a disorder-generating combination of these otherwise functional elements of culture–mind–brain may be emerging.

VULNERABILITY AND STRESS IN THE CULTURE– MIND–BRAIN

Let us now trace the course of mental disorder as it emerges within the culture–mind–brain. We would want to know what makes a person like

Hana vulnerable. Clinical psychology provides us with a set of empirically based models describing mental disorders as resulting from complex interactions between preexisting vulnerability factors and environmental triggers, such as life stress or trauma (Belsky & Pluess, 2009; Monroe & Cummins, 2015). Long before symptoms emerge, some people are at risk for experiencing mental disorder due to factors that range from their biological makeup (e.g., genes) to the socioeconomic or cultural systems in which they live (e.g., racial group marginalization). Although vulnerability factors have generally been studied at a single level, we shall highlight cases in which these factors are best understood in a multilevel way. Indeed, some of the best-researched vulnerability factors, namely, personality traits such as neuroticism or impulsivity, are grounded in robust literatures that include biological, psychological, and sociocultural contributions (Krueger & Tackett, 2003).

Vulnerability at the Brain Level

One possibility is that Hana may be genetically vulnerable to distress. Although behavioral genetics studies have been criticized for their reliance on culturally homogeneous samples (see Duncan et al., 2014), the overall conclusion that mental disorders are shaped in important ways by genes is uncontroversial. The extent of genetic contribution differs disorder by disorder, with a relatively low contribution for some (e.g., major depression) and a relatively high contribution for others (e.g., bipolar disorder) (McGuffin et al., 2003; Sullivan, Neale, & Kendler, 2000). These findings are reflected in a reverse pattern for the magnitude of cross-cultural differences in prevalence and symptomatology, with considerably higher cultural variation for major depression than for bipolar disorder (Weissman et al., 1996). Although cultural factors play a role in most forms of mental illness, their impact is lower for disorders with relatively high heritability.

Although genetic characteristics are distributed differently in different populations, it is important to remember that the genotype and biological phenotype are not deterministic in how they translate into specific symptoms of psychopathology (see Sasaki, LeClair, West, & Kim, 2016). Environmental influences shape gene expression, and habitual behaviors

and ways of processing information affect patterns of brain activation. Consider animal models demonstrating that the rearing environment shapes behavioral outcomes of genes relevant to mental disorders (e.g., Perez-Sepulveda et al., 2013; Suomi, 2006). In one study, rats were selectively bred to be high or low in their response to stressors and rewards (Perez-Sepulveda et al., 2013). Genetically vulnerable rats uniquely benefited from the presence of familiar cage-mates and from exposure to an enriching environment with lots of toys, as evidenced by increases in these vulnerable animals' positive vocalizations. Similarly, cultural environments modulate the ways in which genetic characteristics affect emotions and behavior, producing patterns of cross-cultural differences that do not map onto genetic differences in a simple one-to-one way (for a review, see Sasaki et al., 2016).

Culture–gene interactions have been examined in studies comparing populations of people with known distributions of genetic characteristics, as well as studies comparing people with different polymorphisms of genes known to be associated with different forms of mental disorder. At the level of populations, we know groups that have long inhabited the geographic region of East Asia show high levels of genetic markers of social sensitivity relative to other groups (see Way & Lieberman, 2010). One might expect that these higher rates of genetic vulnerability would lead to higher rates of internalizing disorders in this region. Instead, these rates are lower rather than higher. This is thought to be due to the protective role of collectivistic cultural practices that promote regulation of social stressors and social pain (Chiao & Blizinsky, 2010). Outside of collectivistic cultural contexts, the genetic risks may produce higher levels of distress. Indeed, people of East Asian heritage who have lived in North America for longer periods of time show higher rates of depression than more recent migrants (Tan, 2014).

Studies examining these questions at the individual level also suggest that culture and genes interact to shape indices of mental health. For example, studies conducted in Brazil by Dressler and colleagues suggest that the severity of people's depressive symptoms is predicted by their genetic risk for depression (as indicated by a 5-HT_{2A} receptor polymorphism), their levels of experienced stress (as indicated by their reports of experienced childhood adversity), their local environment (i.e., their neighborhood), and

the larger sociocultural context (i.e., the degree of fit between each person's view of his or her family and cultural consensus on this subject among Brazilians) (Dressler, Balieiro, Ribeiro, & Santos, 2009; Dressler, Balieiro, de Araújo, Silva, & dos Santos, 2016). These and other recent studies suggest that the impact of brain-level vulnerabilities depends in part on the ways in which the brain is affected by the person's thinking, feeling, and relating to others in his or her cultural context.

Of course, Hana's brain functioning may also be affected by nongenetic factors. There is growing evidence that the digestive system may be a long-neglected locus of vulnerability to mental disorders (Forsythe, Sudo, Dinan, Taylor, & Bienenstock, 2010). There is increasing reference to the "brain-gut" axis, with the gut microbiome being implicated in depression, anxiety, and schizophrenia (Dash, Clarke, Berk, & Jacka, 2015; Dinan, Borre, & Cryan, 2014; Foster & Neufeld, 2013). Given regional variations in the prevalence of specific microbiota, along with dietary differences, there is a potential pathway here toward another source of cross-group variation in vulnerability to mental disorder (Yatsunenکو et al., 2012). Indeed, other aspects of diet have already been shown to play such a role (Peet, 2004). One example is that of omega-3 fatty acids, which are found especially in seafood and affect brain functioning (Hibbeln, 2002). Very low consumption of seafood is associated with heightened risk of bipolar disorder (Noaghiul & Hibbeln, 2003). Countries vary not only in access to fish but also in dietary habits (Rozin, Ruby, & Cohen, [Chapter 17](#), this volume): Some have high fish consumption (e.g., Iceland, Korea), whereas others do not (e.g., landlocked Switzerland, but also New Zealand). These differences are associated with different rates of lifetime vulnerability to bipolar spectrum disorders, ranging from a low of 0.2% in fish-loving Iceland to a high of 5.1% in fish-avoiding Switzerland.

Vulnerability at the Mind Level

Hana may also become vulnerable to distress by virtue of how she thinks, feels, and behaves. In some cases, heightened vulnerability to mental disorders can begin with habitual mind-level processes; cognitive vulnerabilities are a widely studied example (Mathews & MacLeod, 2005).

For instance, the ways people appraise stressful events and their own symptoms have important implications for mental health in the wake of severe traumatic events. Those who experience such events and detach or attempt to “mentally undo” them are more likely to develop posttraumatic stress disorder (PTSD) than those who do not employ these cognitive strategies (Dunmore, Clark, & Ehlers, 1999). A similar tendency to suppress one’s emotions spontaneously is associated with symptoms of anxiety and depression (Ehring, Tuschen-Caffier, Schnülle, Fischer, & Gross, 2010; Moore, Zoellner, & Mollenholt, 2008). Additional vulnerabilities, such as inadequate social support or heightened levels of criticism from family members, emerge as (dys)functions of the extended social mind (e.g., Butzlaff & Hooley, 1998).

As with brain-level vulnerabilities, vulnerabilities in the mind can be modulated by culture. Data supporting the previous examples were collected in North American or Western European cultural contexts. Cross-cultural comparisons suggest, however, that at least some of the impact of these vulnerability characteristics is culturally shaped. The tendency to suppress emotions, known to be associated with mental illness for European Americans, does not appear to be as dysfunctional in people socialized in East Asian cultural contexts (e.g., Su, Lee, & Oishi, 2012). Family criticism of a client predicts a problematic trajectory of severe mental illness among European Americans, but not among Mexican Americans (López et al., 2004). In each case, the effects of potential intrapersonal and interpersonal vulnerability factors are shaped by their cultural meanings. The need for Hana to suppress her painful emotions or to tolerate criticism by a family member may violate norms of emotional and interpersonal functioning in European American cultural contexts, but not in East Asian or Mexican contexts. The deleterious (vs. benign or even beneficial) effects of these experiences on Hana would depend on how they fit with her cultural models of normality.

Vulnerability at the Culture Level

Beyond adding nuance to vulnerability stories told at the brain or mind levels, there are scenarios in which the level of culture plays the primary

role. The cultural context can confer vulnerability or resilience to mental illness onto people like Hana by promoting models of thinking, emotions, or behavior that may prove dysfunctional, either generally or at a particular point in history. Cultural meanings and practices have in many cases evolved to promote group identity and survival, and may do so at the expense of individual well-being. What is functional for many or even most people in a group may be dysfunctional for those who are tempted to drink, starve themselves, or chase ephemeral happiness. The ever-increasing levels of self-esteem and confidence in North American cultural contexts fit well with the psychological needs fostered by increasing levels of individualism (Twenge, Konrath, Foster, Campbell, & Bushman, 2008). Yet, although this cultural tendency does not harm (and may even benefit) many in a population, it is associated with important relational and motivational costs (Crocker & Park, 2004). Consider generational increases in the prevalence of narcissistic personality disorder (Stinson et al., 2008), a syndrome with dire interpersonal consequences (Miller, Campbell, & Pilkonis, 2007), or the ways in which increasing residential mobility has potential negative consequences for people low on trait extraversion (Oishi, Krochik, Roth, & Sherman, 2012; Oishi & Schimmack, 2010).

Another example of culture-level vulnerability comes from research on the use and abuse of alcohol. Hana's risk of abusing alcohol would depend on local consumption norms. A child born in some cultural contexts, such as those in the Middle East or Central Asia, has a much lower risk of developing alcoholism than a child born in other cultural contexts, such as those in Eastern Europe. In 2010, prevalence rates for alcohol dependence ranged from well under 1% for Egypt or Saudi Arabia to over 9% for Russia and Belarus (World Health Organization, 2014). These cultural contexts foster different drinking norms and alcohol expectancies, or beliefs regarding potential outcomes of alcohol for the self and others. Positive alcohol expectancies, such as believing that drinking will make one feel better, are known to predict drinking and alcohol-related problems and mediate the effects of temperament on these outcomes (Corbin, Iwamoto, & Fromme, 2011). Eastern European contexts foster a view of drinking as a culturally acceptable or even celebrated way of socializing and regulating negative emotions (e.g., Pesman, 1995), thereby encouraging use and abuse of alcohol (Popova, Rehm, Patra, & Zatonski, 2007). In contrast, Middle

Eastern cultural contexts are shaped by Islamic religious norms that strongly discourage use of alcohol. These norms affect drinking behavior at many levels, from intrasubjective attitudes about alcohol consumption to legal sanctions against drinking, to the availability of alcoholic products.

In addition to temporally stable vulnerabilities, there are also examples of spikes in vulnerability to mental disorder during cultural transitions. Classic models of social change by Durkheim (1970) and Merton (1938) proposed that rapid social change contributes to psychological and social difficulties. Chandler and Lalonde (1998), for example, found that the epidemic of suicides among First Nations in Canada is not evenly distributed; rather, it is linked to the extent to which a given community suffered a loss of cultural continuity as a result of colonization. Bands that retained or regained control over local affairs had suicide rates much closer to European Canadian norms, whereas those that lost much of this control had rates that were up to hundreds of times higher. A similar pattern of results emerged in a comparison of bands with varying degrees of success in preserving indigenous languages, another proxy for cultural stability (Hallett, Chandler, & Lalonde, 2007).

Hana may also become vulnerable to mental disorder due to being caught in between the valued cultural models in which she was raised and newer models emerging due to socioeconomic shifts. During times of change, traditional culturally valued models of behavior may become poorly suited to the new circumstances, leaving some people, such as those who are younger and have fewer resources, with limited means to succeed by enacting these models. Consider Japan, a rapidly changing society that is grappling with stresses imposed by globalization, economic recession, and transition to a postindustrial economy. In the last few decades, these changes have engendered a shift away from traditional interdependent models of the self, particularly among disenfranchised Japanese youth (Toivonen, Norasakkunkit, & Uchida, 2011). This shift has been psychologically costly, placing youth who are more culturally deviant than their peers at heightened risk for social disengagement and psychological distress (Norasakkunkit & Uchida, 2014).

Ethnic/minority status might further contribute to Hana's vulnerability to mental disorder, particularly if she is identified by others as a member of a socially devalued group (Mendoza-Denton & Worrell, [Chapter 28](#), this

volume). One striking observation replicated in a number of countries involves higher rates of psychotic disorders in minority populations, particularly black minorities in majority white cultural contexts. Relative risk varies markedly when majority white and minority black groups are compared (Cantor-Graae & Selten, 2005), even though there is no evidence for increased risk in black majority societies. Some of this discrepancy may be attributable to misdiagnosis, particularly overinterpretation of contextually appropriate mistrust (Whaley, 2001). Nonetheless, several teams of researchers, particularly in Europe, have found that risk for psychotic disorders is associated with experiences of social defeat and marginalization: Biologically vulnerable people are much more likely to develop psychosis under chronically adverse social conditions (Selten, van der Ven, Rutten, & Cantor-Graae, 2013).

Just as culture shapes expression of brain- and mind-level vulnerabilities, brain and mind in turn constrain cultural shaping of mental disorder. Our evolutionary heritage limits the ways in which our thoughts, emotions, and behavior go awry, and encourages stability and adaptation. For instance, although manifestations of anxiety disorders differ across cultural contexts, they are nonetheless constrained by the ways in which the brain and nervous system process threat (e.g., Öhman, Dimberg, & Öst, 1985). Even those contexts wherein threats are common or even culturally desirable (e.g., Mapuche parents in Chile encouraging their children to take risks and encounter potential threats to gain independence; Murray, Bowen, Segura, & Verdugo, 2015) do not produce anxiety symptoms that violate these constraints. Examples of such constraints include the fact that anxiety drives attention, or that high levels of arousal are sustainable only for very brief periods of time.

Similarly, mind-level factors can limit the effects of cultural environments on mental disorder. Studies of people who live in the most adverse contexts suggest that only a minority develops serious mental disorders. Psychological resilience is common. Researchers attribute this resilience to normal functioning of psychological and interpersonal adaptation systems, with most people displaying effective problem solving, positive emotions, social support provision, and meaning maintenance in the face of significant stressors (Bonanno, 2004; Heine, Proulx, & Vohs, 2006; Masten, 2001). For example, in one study of children living in adverse

circumstances, children's intelligence and quality of parenting they received limited the effects of adverse environments on their antisocial behavior (Masten et al., 1999). In summary, substantial heterogeneity in mental disorder can be attributed to culture, but this variability is not boundless. Vulnerabilities at one level of culture–mind–brain constrain and shape, and are constrained and shaped by, vulnerabilities and resilience at other levels.

Stressors and Triggers

Vulnerability factors alone do not fully account for the emergence of mental disorder. Perhaps there are other people in Hana's social circle who will never develop a mental disorder despite a strong genetic loading or tendency to ruminate. In order to understand the emergence of actual symptoms of distress, vulnerability factors need to be considered in combination with environmental triggers. These triggers include exposure to prenatal stressors (e.g., viral illnesses) during critical periods of brain development, stressful life events (e.g., trauma), as well as chronic stress (e.g., poverty). Many ubiquitous sources of stress, such as climate and the resulting likelihood of natural disasters, access to health care, economic and political systems, and geopolitical conflict are interwoven with culture (e.g., Gelfand et al., 2011; S. Schwartz, 2006; Talhelm & Oishi, [Chapter 4](#), this volume). Even seemingly random life events, such as fatal traffic accidents, are not distributed equally across cultural contexts (World Health Organization, 2015), and are dependent on cultural factors (e.g., norms of driving behavior; Özkan, Lajunen, Chliaoutakis, Parker, & Summala, 2006).

Jointly, stress and vulnerability allow us to better account for individual and cultural differences in symptom levels. For example, across cultural contexts, common forms of internalizing disorders are associated with lower socioeconomic status (Steptoe, Tsuda, & Tanaka, 2007; Van de Velde, Bracke, & Levecque, 2010). Although there is no doubt that mental disorder can reduce educational and financial attainment (Kessler, Foster, Saunders, & Stang, 1995), limited access to socioeconomic resources uniquely contributes to development and maintenance of symptoms (e.g., Costello, Compton, Keeler, & Angold, 2003), and helps account for cultural differences in internalizing distress (Van de Velde et al., 2010).

In summary, prior to developing symptoms of mental disorder, people vary in terms of their physiological, psychological, and cultural vulnerabilities. The local sociocultural context also contributes to their exposure to stress. Hana's likelihood of developing symptoms of mental disorder depends in part on these factors. Different distributions of vulnerability factors and stressors across cultural contexts can help us account for cultural group differences in prevalence and expression of the common types of mental disorders. Yet the story of how cultural context shapes mental disorder only begins here: Vulnerability and stress factors are far from the only mechanisms shaping cultural variation in psychopathology. As Hana develops distressing symptoms, she will not experience them in a cultural vacuum.

Many empirical examples suggest that even when people depart from cultural norms, they tend to do so in ways that are shaped by these norms. For example, although paranoid delusions are common in schizophrenia across cultural contexts, their content differs (Tateyama, Asai, Hashimoto, Bartels, & Kasper, 1998). Delusions of being poisoned or delusional guilt are more common in Austria and Germany than in Japan; the opposite is true for delusions of being slandered. Similarly, although auditory hallucinations, especially hearing voices, are much more common in patients with schizophrenia than hallucinations involving other sensory modalities, the likelihood of a patient experiencing particular types of hallucinations differs markedly across cultural contexts (Bauer et al., 2011). Roughly half of all patients in the West African countries of Ghana and Nigeria report having experienced visual hallucinations within the last year. Moreover, they tend to experience them relatively often, on average about two to three times a year. The same symptom is very rare in Pakistan, with fewer than one in 25 patients reporting this symptom, and in Georgia, just shy of one in 10. When Pakistani or Georgian patients do report this symptom, it is relatively rare, occurring only once a year on average. These differences are not easily reducible to vulnerability and stress factors. In the case of paranoid delusions, we may want to know more about Austrian, German, and Japanese cultural scripts of psychosis to make sense of the observed differences. Let us consider what is known about symptom- and syndrome-generating scripts that might add to existing work on vulnerability and stress.

THE ROLE OF CULTURAL SCRIPTS IN SHAPING PSYCHOPATHOLOGY

In order to gain better purchase on the emergence of Hana's symptoms, and the personal and social responses to these symptoms, we need to consider local understandings of health, suffering, and pathology. Although not everyone has firsthand experience with mental disorder, we are all familiar with representations of what it means to be healthy and ill in our local social world. Consider Hana's potential encounters with these ideas while growing up. Perhaps she overheard adults talking about someone's low spirits, witnessed reactions to a person who was intoxicated, or read about people acting in hard-to-comprehend ways. She may have seen public health education posters or been explicitly taught about mental health in school. The information available to her would depend on her cultural context. We begin with these personal and consensual beliefs, understood as "cultural scripts," before turning to the ways in which these scripts shape the emergence and maintenance of mental disorder.

Personal and Consensual Beliefs about Distress

To better understand Hana's beliefs about mental disorder, one would need to learn about cultural scripts common in her cultural context(s). "Cultural scripts" are sequentially arranged schemas that are intersubjectively shared, which means that they tap into ideas of what other people know and believe in a given cultural context (Wan, Torelli, & Chiu, 2010). These scripts guide the meanings (e.g., beliefs, values, expectations) and practices (e.g., consensually understood behaviors, such as speech) in a given conceptual domain. Many of these scripts are normative: People who act in accordance with a normative cultural script are acting in a socially approved manner. Deviant cultural scripts, in contrast, involve that which is still comprehensible but is understood as abnormal and undesirable (Chentsova-Dutton, Ryder, & Tsai, 2014). For example, a Kerala script of teenage suicide is recognized by most people in this South Indian cultural context and is understood as tragic and abnormal (Chua, 2012). A subset of deviant scripts pertain to mental disorder: They shape where we draw the line between

health and illness, how we recognize a problem, what we call it, and how we talk about it (or avoid talking about it). They inform us about possible causes, signs and symptoms, seriousness, and anticipated course. Finally, they provide us with guidance about whether to seek help, how to do so, and what treatments might be most effective.

Prior work in cultural psychiatry has used several related constructs to describe local understandings of symptoms and etiology (formerly “culture-bound syndromes,” replaced with “cultural syndromes”; Alarcón, 2014), etiological beliefs about particular forms of suffering, and consensual models shared by members of a given community about why people suffer in particular ways (“explanatory models”; Kleinman, 1977), the ways in which distress is communicated to others to facilitate social support while minimizing stigma (“idioms of distress”; Nichter, 2010), and personal accounts of suffering (“illness narratives”; Groleau, Young, & Kirmayer, 2006). We prefer the construct of cultural scripts due to its ability to capture both intrasubjective and intersubjective understandings of mental disorder that are encoded and enacted in cultural environments.

To gain better purchase on the relevance of cultural scripts to health concerns, let us briefly consider the scenario in which Hana has experienced a head trauma. Without ever having a concussion, most people are familiar with a script of postconcussive symptoms, including expectations that one will experience headaches and feel anxious after head trauma (Mittenberg, DiGiulio, Perrin, & Bass, 1992). Many competing sets of shared scripts of a health condition (e.g., folk categories of sickness, biomedical models offered by the health care establishment) may be available within a single cultural context. Yet cultural scripts are often inaccurate. People’s expectations of postconcussive symptoms are at odds with the actual postconcussive changes observed by neurologists (Mittenberg et al., 1992). Since people are not simply interchangeable representatives of their cultural groups, these scripts also may or may not accurately reflect any given person’s private understanding of his or her own symptoms. We nonetheless believe it is important to study scripts, because they can tell us about intersubjective understandings, framing people’s interpretation of their own and other people’s symptoms and organizing their ability to understand the responses of others to their own distress.

Deviant scripts can only be fully understood in reference to normative scripts (Chentsova-Dutton et al., 2014); that is, to understand symptoms in a particular cultural context, it is important to consider the ways in which these symptoms conform to or deviate from how one is expected to function as a healthy community member. For example, cross-national research on autism yields differences in parental reports of symptoms (see Mandy, Charman, Puura, & Skuse, 2014). A leading hypothesis is that these differences may be due in part to variation in beliefs about normal development; after all, nonclinical samples from different cultural contexts differ in their endorsement of traits associated with the autistic spectrum (Wakabayashi, Baron-Cohen, Wheelwright, & Tojo, 2006). Some mental disorders may even be associated with psychological characteristics that can only be understood in reference to normative scripts. For example, depression is associated with decreased emotional expressiveness in European Americans, but increased emotional expressiveness in Asian Americans. These two correlates of depression seem diametrically opposed, but in both cases they reflect a deviation from normative scripts for emotion expression in each cultural context (Chentsova-Dutton et al., 2007; Chentsova-Dutton, Tsai, & Gotlib, 2010).

As culture changes over time, so do illness-relevant scripts, and as they shift, they trigger reciprocal changes in normative scripts. For example, at the time of reunification with West Germany, many East Germans reported that the official symptoms of major depression did not fit any of the East German scripts of mental illness (Beck, Matschinger & Angermeyer, 2003), describing these symptoms as examples of unfortunate but normative behavior caused by personal problems or life crises. As deviant scripts (i.e., for major depression) available to East Germans changed over time due to contact with West Germany, more and more residents of the former East Germany became convinced that these symptoms signaled pathology. In the process, East German models of normative behavior were adjusted to exclude characteristics such as melancholic mood and withdrawn behavior. Another example is provided by the case of broadening diagnostic criteria for autism spectrum disorders (Gernsbacher, Dawson, & Hill Goldsmith, 2005). As the diagnostic criteria expanded, the public experienced these changes as evidence of a terrifying epidemic of autism. Members of the public, teachers, and parents were also increasingly likely to understand a

broader range of behaviors as indicative of autism and hence pathological, altering their perspective on milder symptoms that were previously considered normal (Gnaulati, 2013; Molloy & Vasil, 2002). A number of adults reinterpreted their own social functioning and shifted from seeing their own behavior as quirky but normal to autistic (see Limburg, 2016, for one such example). Meanwhile, some researchers in disability studies sounded the alarm regarding the potential negative consequences of downward expansion, toward viewing larger swaths of the autism spectrum as pathological (Moloney, 2010).

Conversely, changes in normative scripts can prompt changes in deviant scripts. For example, modernization in China, combined with increasing exposure to Western ideas, has fostered changes in beliefs about shyness. Whereas shy children used to fit well with traditional Chinese normative scripts, shyness is increasingly understood as problematic in Chinese society. Although shyness among elementary schoolchildren was associated with social and academic achievement as recently as 1990, it was linked to internalizing and externalizing problems by 2002 (Chen, Cen, Li, & He, 2005). Notably, shyness continued to be associated with markers of positive adjustment in more traditional rural schools in China, but increasingly it was linked with maladjustment in urban areas undergoing rapid cultural change and modernization (Chen, Wang, & Wang, 2009).

Cultural scripts of illness are important to consider even for disorders with known physiological etiology that is largely independent of culture (e.g., diabetes; C. Smith, 2012). For example, the symptoms of myopia are similar across cultural contexts, yet cultural scripts of nearsightedness vary substantially—and can have real-world ramifications. Consider Chentsova-Dutton's experiences in Russian and American cultural contexts. In Russia, nearsightedness is thought to signal vulnerability for further eye disease. A typical recommendation would be to refrain from high-impact exercise for fear that strain might further damage vision. Nearsightedness is partially attributed to the person's behavior (e.g., not protecting the eyes). In the background there are long-standing assumptions linking glasses with social class membership. In other cultural contexts (e.g., Cambodia), such stereotypes are even more salient due to a recent history of persecuting people wearing glasses, because such people were assumed to be educated and privileged (Etcheson, 2005). In contrast, the American script for

nearsightedness largely attributes this problem to genetic factors and does not point to salient social or practical contingencies of its symptoms. Cultural variations in scripts can organize a person's model of themselves and their relationships with others vis-à-vis their symptoms and their expectations for the future. Scripts are even more important to examine in the realm of mental disorders, as psychological functioning is not independent of our understanding of it. People do not become significantly more nearsighted in response to a cultural script, but they may feel and exhibit more emotional, psychosomatic, cognitive, or behavioral symptoms that fit with culturally or personally salient scripts (Barsky & Borus, 1999; Mittenberg et al., 1992).

We contend that cultural scripts shape the beliefs of sufferers and others in their local social world about what is going on and what one ought to do about it. Yet we would push this claim about culture's centrality much further. When a vulnerable person such as Hana begins noticing something awry with her body or thoughts, recruitment of salient scripts may potentially play an essential role in actually generating and then maintaining symptoms. It is to this possibility that we now turn.

Emergence and Maintenance of Disorder

At any given moment, our bodies and minds produce myriad potentially discernible somatic, cognitive, and emotional changes. Much of the time, we are barely aware of them, although they may enter our consciousness when they become particularly intense or when other sensations are limited (Pennebaker & Brittingham, 1982). If you stop reading this chapter for a few seconds and pay attention to your body or your mind, you will likely notice twitches, tensions, or nagging thoughts that were not on your mind just a moment ago. Some of these experiences are surely trivial; others may be noteworthy, annoying, or even alarming. Even healthy people experience a significant number of *potentially symptomizable experiences* (Ryder & Chentsova-Dutton, 2015), ranging from changes in mood and energy level all the way to hallucinations, dissociations, intrusive thoughts, and compulsions (e.g., Flett, Vredenburg, & Krames, 1997; Gibbs, 1996; Johns & Van Os, 2001; Kihlstrom, Glisky, & Angiulo, 1994; Radomsky et al., 2014).

Let us compare the full set of experiential changes that may be noticed by a person like Hana to the full set of stars that are visible from a particular location in the night sky on a particular night. Just as the number of visible stars depends on the observer's visual acuity, the stars' apparent brightness and weather conditions, the number of discernible physical and psychological sensations observed by Hana depends on her interoceptive and introspective abilities, the intensity of her sensations, and the presence of salient distractors. Both sets are very large, albeit finite; in both cases, only a subset will be noticed. Just as one does not attend to or remember all visible stars, one does not attend to or remember all available somatic and psychological changes.

The extent to which stars or experiential changes enter into consciousness and become registered as noteworthy depends on a combination of bottom-up factors, such as their novelty and intensity, as well as top-down factors, such as available schemas that can organize and scaffold attention to some stars or changes over others. In the case of stars, people rely on constellation schemas. There are stories behind each constellation, guiding perception, interpretation, and memory (e.g., "Orion, the hunter, is so close to Lepus, the hare, because the former is hunting the latter"). Although these schemas are constrained by the visual characteristics of the stars themselves, they also differ culturally. The ancient Chinese organized their constellations differently from the ancient Greeks, although both sets feature some of the brightest stars in the night sky. The Inca, looking up at the star-dense Milky Way in the Southern Hemisphere sky, saw constellations in the sparsely populated dark spaces (*yana phuyu*) between bright stars (Urton, 1981); nonetheless, all of these groups were constrained by the actual arrangement of light and dark in the night sky.

Similarly, although scripts of mental disorder are constrained by the evolutionarily shaped responses of our bodies and brains to physical or environmental disruptions, they are also culturally shaped. A common script for depression in European American cultural contexts emphasizes psychological causes and cognitive symptoms, such as deficits in the ability to think clearly (Karasz, Garcia, & Ferri, 2009; Ryder et al., 2008), whereas counterpart scripts in China or India foreground somatic symptoms, such as "sinking heart," fatigue, and weakness (Dere et al., 2013; Kleinman, 1977; Krause, 1989; Pereira et al., 2007). Yet all these scripts acknowledge sleep

disruption as a salient and potentially universal “bright star” symptom of depression.

Hana is likely to utilize scripts available in her cultural context(s) to monitor, detect, and interpret changes in her bodily sensations, emotions, cognition, and behavior. Scripts are also likely to affect how she might experience these symptoms, encode and recall her experiences, and communicate them to others, facilitating recall of script-consistent information (Bower, Black, & Turner, 1979; Sentis & Burnstein, 1979; Petersen, Schroijen, Mölders, Zenker, & Van den Bergh, 2014). Even minimal categorical information about classes of sensations is known to affect how they are experienced and remembered (Petersen et al., 2014). Although people are generally poor at remembering their own symptoms after a delay (e.g., Wells & Horwood, 2004), they may be more likely to remember symptoms that fit the script (at times falsely) than those that do not. Indeed, preexisting and experimentally induced scripts affect memory of psychological processes (Robinson & Clore, 2002), including reports of symptoms (see Barsky, 2002, for a review). For example, women’s descriptions of menstrual symptoms are shaped more by their scripts of premenstrual syndrome (PMS) than by their in-the-moment experiences of discomfort in the days prior to menstruation (Boyle & Grant, 1992; McFarland, Ross, & DeCourville, 1989).

Salient scripts may also reveal or amplify existing symptoms and even trigger new ones. By conditioning responses to script-associated cues and directing attention toward some potentially symptomizable experiences and away from others, scripts can help convert these experiences into full-blown symptoms by increasing readiness to perceive script-consistent symptoms. Just as one may search the sky for a star that is known to be part of a given constellation, one may scan sensations, thoughts, the local social environment, and so on, for known characteristics of a particular disorder, thereby speeding up the process of identification and increasing the chances of labeling the scripted syndrome accordingly—if not necessarily “accurately” (Lange & Fleming, 2005; Pennebaker & Skelton, 1981). These processes trigger shifts in perceptual biases and ensure that experienced patients detect and process their symptoms differently than do novices. Accumulating research demonstrates that our expectations and conditioned associations powerfully affect a wide range of perceptual processes,

including perception of emotional expressions and experiences of taste, pain, and somatic changes, such as chest tightness, to mention just a few (Koyama, McHaffie, Laurienti, & Coghill, 2005; Plassmann & Weber, 2015; Van den Bergh, Stegen, & Van de Woestijne, 1997; for a review, see K. Schwarz, Pfister, & Büchel, 2016).

Furthermore, the high prevalence of medically unexplained symptoms and syndromes, and documented cases of mass hysteria, show that vulnerable members of a population are capable of developing symptoms and entire syndromes in response to salient cultural representations (see Boss, 1997; Rief & Broadbent, 2007). This process has been well-characterized in the literature on the “nocebo effect,” or the tendency to develop and/or intensify symptoms in response to negative expectancies (Benedetti, Lanotte, Lopiano, & Colloca, 2007; Lang et al., 2005). Nocebo effects have been observed in controlled laboratory-based studies for a number of symptoms, ranging from increased pain to sexual dysfunction. Priming people with illness scripts in many cases triggers reports of script-consistent symptoms and risk factors (Lorber, Mazzoni, & Kirsch, 2007; Nakajima & Fleming, 2008; Skelton, Loveland, & Yeagley, 1996; Witthöft & Rubin, 2013). Participants in one study reported experiencing more flu and strep symptoms after being primed by questions about fever and sore throat, prototypical symptoms of these illness scripts (Skelton et al., 1996). Factors such as somatic awareness, emotional arousal, and high levels of trait negative emotions/neuroticism are known to increase the likelihood of symptom amplification and symptom generation (Barsky, 2002; see Van den Bergh, Bogaerts, & Diest, 2015 for a review).

Therapeutic approaches designed to teach vulnerable people, particularly those with higher levels of the aforementioned factors, what symptoms to expect may therefore produce increased levels of such symptoms among some of the targets. For example, symptoms of PTSD tend to increase and/or persist following “critical incident stress debriefing,” an intervention approach that educates survivors about potential symptoms of PTSD soon after the trauma (Gist, 2015). This tendency may be due in part to introduction of a new illness script to vulnerable individuals (Bootzin & Bailey, 2005). Emerging studies suggest that people from cultural contexts that encourage attention to the body (i.e., East Asian and West African contexts) are less accurate, although more confident, when detecting and

tracking actual bodily changes (e.g., heartbeat; Chentsova-Dutton & Dzokoto, 2014; Ma-Kellams, Blascovich, & McCall, 2012). It may be that by encouraging attention to the body, these contexts actually encourage attention to culturally salient scripts of bodily changes rather than to actual bodily changes. It remains to be seen whether these differences translate into higher likelihood of generating symptoms in response to cultural scripts.

The normative and deviant cultural scripts held by family members, friends and acquaintances, and the community at large may also contribute to the maintenance of a mental disorder. After all, many symptoms are public events: noticed, discussed, evaluated, tolerated, and/or punished by others. The consequence is that social meaning is ascribed to being sick in a particular way. Consider one of the best-known patterns of findings in culture and mental health, from the literature on schizophrenia. People experiencing a first episode of this disorder respond better to treatment and have a more benign course of illness if they live in low-income developing countries, such as India or Algeria, relative to wealthier developed countries, such as the United Kingdom or Japan. This pattern is puzzling given the fact that the latter countries offer more comprehensive and up-to-date psychiatric care than do the former (Hopper & Wanderling, 2000; Novick et al., 2012; Sartorius et al., 1986; for a review, see Isaac, Chand, & Murphy, 2007; but for a contrary view, see Patel, Cohen, Thara, & Gureje, 2006). Despite the first reports of this pattern appearing over four decades ago (e.g., in Mauritius; Murphy & Raman, 1971), surprisingly little progress has been made in identifying cultural factors that shape these differences in outcomes. Although variations in stigmatizing attitudes have been ruled out as a potential explanation (Pescosolido et al., 2015), the influence of other cultural factors remains underresearched. Continued inclusion in the community, for example, through holding a socially meaningful role, has been suggested as a potential explanation. This experience is in marked contrast with the social defeat more common in wealthier developed countries—and especially, as previously discussed, in devalued minority groups (Luhmann, 2007).

In summary, there is a possibility that being reminded of a familiar deviant script may affect Hana's symptoms. Some people respond to cultural representations of physical and psychological symptoms by noticing bodily and psychological changes consistent with these representations and

emphasizing them in their own reported experiences. Although some of these sufferers may be motivated by strategic concerns, such as reporting or denying a particular symptom to gain access to health care resources or to avoid shame, symptoms can also emerge with little to no conscious intent or awareness. Their emergence, in turn, takes place in a social world in which the symptoms are further shaped by the actual, anticipated, or perceived reactions of others.

Disordered Loops

Finally, Hana's potentially symptomizable experiences may combine with normal and abnormal cultural scripts, the interpersonal reactions of others, the institutional structures in a society, and so on, to generate and sustain symptoms in vicious self-perpetuating cycles. For example, her anticipatory anxiety about speaking in public might combine with consensually held beliefs about the consequences of poor performance, leading to heightened physiological arousal symptoms while speaking, such as sweating, stuttering, and trembling hands. These responses might in turn lead to embarrassment and negative interpretations about how other people are judging her ability to speak, leading to more anxiety. On a longer time scale, believing that public speaking experiences will likely end in disaster may lead Hana either to suffer through them (i.e., punishment for engaging in public speaking) or avoid them when possible (i.e., positive reinforcement for avoiding public speaking). Either way, a second loop emerges that helps to maintain the persistence of her symptoms (Ryder & Chentsova-Dutton, 2015).

Attending to, pathologizing, and communicating about certain experiences can create such feedback loops in which attention and response to these experiences leads to their intensification and emergence as full-blown symptoms. One consequence, of course, is to encourage monitoring of these symptoms, potentially worsening them further. This is well-documented for anxiety (D. Clark, 1999), somatic symptoms (Witthöft & Hiller, 2010), and sexual disorders (Barlow, 1986), all characterized by high levels of anxiety about experienced symptoms. Interruption of such loops is the bread and butter of cognitive-behavioral therapies (CBT) for these disorders. Because deviant scripts differ cross-culturally, attention may be

driven to different symptoms, promoting culturally variable dysfunctional loops underpinned by universal mechanisms.

Consider one of the most widely cited articles in clinical psychology. D. Clark (1986) describes panic attacks as catastrophic misinterpretations of physical sensations; for example, people with panic disorder tend to interpret increased heart rate as a sign of possible heart trouble. Perhaps Hana is particularly prone to this interpretation. Given the prevalent belief that heart trouble is dangerous and hence frightening, her anxiety increases. She then attends more closely to chest sensations, but the autonomic arousal that accompanies her rising anxiety leads to additional chest sensations. This pattern requires Hana to hold certain assumptions that in themselves may well be reasonable—that heart trouble is concerning, that a rapidly increasing heart rate could be dangerous and potentially fatal. Now, what if Hana lives in a different cultural context, with different reasonable assumptions? Hinton and colleagues (e.g., Hinton, Um, & Ba, 2001; Hinton, Kredlow, Pich, Bui, & Hofmann, 2013) have described the phenomenon of “neck-focused panic attacks” in Cambodian cultural contexts, focusing on a set of folk physiological beliefs surrounding *khyal*, or energy that flows through the body. The neck is seen as particularly vulnerable: Rapidly rising *khyal* can lead to blockages in the neck, causing stiffness, pain, and ultimately death from burst blood vessels. Neck stiffness therefore has the potential to be catastrophically misinterpreted as dangerous and potentially fatal.

Another example comes from the *koro* script, widely known by various names in a number of Asian and West African cultural contexts (Chowdhury, 1996; Dzokoto & Adams, 2005). Sufferers of *koro* report that their genitals are shrinking or disappearing into their bodies. Often, another person is accused of causing these symptoms via witchcraft. The full-fledged experience of *koro* depends on having access to cultural scripts that infuse these symptoms with meaning. Although isolated cases do occur in Western cultural contexts, these contexts lack deviant scripts that explain them (Malinick, Flaherty, & Jobe, 1985). These cases do not spread. Knowing that situational fluctuations in the size and appearance of genitals may potentially signal trouble, and, in response, attending to these changes and responding to them as threatening, generates loops that reinforce the symptoms (Simons, 1983). Moreover, as the script includes the belief that

koro can travel in waves through geographical areas, awareness that an outbreak is occurring and that cases have been observed in neighboring communities can further heighten attention to signs of genital shrinkage. Shared beliefs about how *koro* moves through populations contribute to it moving through populations in exactly those ways.

Looping may also unfold in interpersonal contexts. For instance, insecure romantic attachment is known to be associated with lower perceived support from one's romantic partner, which in turn contributes to dissatisfaction with relationships and depressive symptoms. A comparison of Hong Kong and the United States suggests that although avoidant attachment is linked to poor relationship outcomes in both societies, the strength of some of these relationships (e.g., between avoidant attachment and low perceived support) is stronger for people in more interdependence-promoting Hong Kong relative to those in the more independence-promoting United States (Mak, Bond, Simpson, & Rholes, 2010). It is likely that these results reflect interaction dynamics between the two partners as they unfold in their cultural context. People with avoidant attachment models tend to see their partners as demanding and overbearing in their expectations of closeness. They describe themselves as aloof, and prefer more distance and less mutual dependence. Although some of the specific preferences associated with avoidant dependent styles (i.e., avoiding emotional disclosure) may fit with interdependent models of relationships, this broader avoidant way of viewing close relationships clashes with expectations promoted in interdependent contexts. While avoidant people across cultural contexts may reject their partners' overtures for closeness, partners of highly avoidant individuals in Hong Kong may gradually become more upset, more critical, and less likely to respond with support given that their cultural context leads them to expect interdependence. This study illustrates the ways in which models of relationships that violate normative cultural scripts of how to be a good partner may be more likely to threaten interpersonal and intrapersonal functioning, thereby triggering interpersonal loops. When examining Hana's symptoms over time, cultural-clinical psychologists would want to observe temporal dynamics of certain symptoms triggering and potentiating one another and of the ways in which Hana's friends and family respond to her symptoms, thereby potentially affecting the symptoms themselves.

Implications for Clinical Research and Practice

All in all, the cultural–clinical psychology approach to mental disorder, with its emphasis on dynamic looping processes, may well serve to broaden our appreciation for the role of culture. It also promises to make life more difficult for researchers, let alone clinicians. The former want well-defined diagnostic groups for comparison purposes; the latter want them for treatment planning; and everyone wants clear and efficient communication. If properly designed, and appropriate to a given context, these categories may have important, albeit limited, functional utility—for self-understanding, professional communication, treatment decision making, insurance reimbursement, public policy debate, and so on—but this does not mean they are natural kinds. We know that psychiatric categories are not fixed; indeed, most of them are not especially categorical (Haslam, Holland, & Kuppens, 2012; Kotov et al., 2017). Clinical science is in flux regarding its conceptualization of mental disorder (Lilienfeld & Treadway, 2016), precisely because symptoms of mental disorder show little evidence of reflecting clear-cut diagnostic categories as they are imagined by clinical communities. While true even of studies conducted within a single society, such as the United States, the problem compounds once we expand across cultural contexts. Looping effects render fixed human categories all but impossible: People notice them, talk about them, write about them, divert funds to (or away) from them, valorize them, and stigmatize them, all in ways that loop back to further shape the category, leading to considerable diversity across cultural–historical contexts (Hacking, 1995; for examples, see Ryder, Zhao, & Chentsova-Dutton, 2017; Sun & Ryder, 2016).

As researchers interested in labeling theory and stigma have long known, part of the experience of being “depressed” or “schizophrenic” is the consequences of knowing that one fits within a particular category, and knowing that others see one as fitting in that category as well (Kroska & Harkness, 2008; Link, Cullen, Struening, Shrout, & Dohrenwend, 1989). We do well to keep this in mind as we turn our attention to help seeking, then, finally, to clinical evaluation and intervention. All of these processes are deeply social. A client’s suffering can be dramatically shaped by the ideas, attitudes, social contingencies, and structural features of the people and institutions encountered throughout the search for healing. Hence, we do

well to consider the possibility that they are shaped in important ways by the cultural context.

PATHWAYS TO HEALING

Not only do deviant cultural scripts include information about the causes and consequences of a given mental disorder, but they also provide prescriptions about what one should do about it. There is considerable cultural variation in what a person is expected to do when emotionally distressed: what reactions are appropriate, at what point is it appropriate to solicit help, how is this most effectively done, what can one realistically expect of another person (Kim, Sherman, & Taylor, 2008; Kim & Lawrie, [Chapter 10](#), this volume)? For example, European Americans are more likely to disclose their problems and/or distress and ask for help than are Asian Americans, a pattern partly due to cultural variation in concerns about burdening others (e.g., Taylor et al., 2004). As a result, European Americans are more likely to psychologically and physiologically benefit from explicit support than are Asian Americans. The reverse is true for implicit support, or face-saving forms of support that involve close social presence but no disclosure of a problem (Taylor, Welch, Kim, & Sherman, 2007).

These models of support are important to our understanding of what people do when they develop troubling symptoms, as they extend to the realm of help seeking. One study that compared Japanese and American students found that Japanese students were more reluctant to seek professional help for hypothetical symptoms of mental disorder than were American students, an extension of a more general reluctance to seek help from close others (Mojaverian, Hashimoto, & Kim, 2013). Furthermore, studies examining beliefs about help seeking among adults suffering from mental disorder indicate that these beliefs are culturally patterned. If Hana is an Ecuadorian suffering from *pena* (Tousignant & Maldonado, 1989), her cultural context may suggest that not only is it important for her to pay attention to her stomach and heart, but also her depression-like symptoms may best be addressed by appealing to those in the community who have wronged her in the past. If, in contrast, she is an immigrant from a South Asian cultural context, she may be more familiar with the notion of tackling

her symptoms by distracting herself or turning to family members to talk about her situation (Karasz, 2005).

Similarly, there is variation in what a provider of help is supposed to do. For example, is unsolicited advice appropriate, or might it lead to an autonomy threat or a loss of face (Chentsova-Dutton, 2012)? In the case of mental disorders, stigma and lack of “mental health literacy” have been identified as barriers to effective treatment (Furnham & Hamid, 2014; Livingston & Boyd, 2010). Although it is important to educate clients about mental health, one needs to be aware of the danger of uncritically assuming that Western perspectives on mental health are the correct ones (Na, Ryder, & Kirmayer, 2016). Regardless, pathways to healing are powerfully shaped by the sufferer’s own beliefs, prevalent assumptions in the sufferer’s local social world, and the expectations of care providers.

Help Seeking and Treatment Seeking

Will Hana seek help for her symptoms? People who believe in negative consequences for speaking up about their distress will, not surprisingly, conceal this distress as best they can. A core set of stigmatizing beliefs about mental disorder can be identified across a wide range of different societies (Boyd, Adler, Otilingam, & Peters, 2014; Littlewood, Jadhav, & Ryder, 2007). Simply holding such beliefs about one’s suffering can worsen the suffering. Moreover, intersubjective beliefs about the stigmatizing attitudes of others predict reluctance to seek help (e.g., Tucker et al., 2013). People might also delay help seeking because they do not actually recognize their suffering as requiring intervention. In recent years, advocates of mental health literacy have argued in favor of public education about mental disorders in order to promote early detection and intervention (Jorm, 2012). These approaches tend to be based on Western understandings, however, pointing to the need to develop a more culturally informed perspective (Na et al., 2016). Caution here is especially warranted given evidence, discussed earlier, that encouraging new cultural scripts may well lead to the emergence of new symptoms.

If Hana decides to disclose her symptoms, to whom might she turn? When suffering cannot be hidden any longer, people across a wide range of

cultural contexts prefer to keep this information within a trusted social network, most often within the family. Doing so protects the family from the stigmatizing reactions of others (Lin, Inui, Kleinman, & Womack, 1982; Pescosolido, Boyer, & Medina, 2013). In Western societies, people from minority backgrounds are particularly likely to do this, and hence underutilize formal mental health services (e.g., Colucci, Szwarc, Minas, Paxton, & Guerra, 2014; Hernandez, Nesman, Mowery, Acevedo-Polakovich, & Callejas, 2009). Moreover, underutilization does not necessarily mean lack of treatment: An apparent delay in accessing standard interventions might be due to reliance on traditional healing practices, which may prove helpful to the sufferer (e.g., Gone, 2013; Kirmayer, 2012). Nonetheless, delays often have deleterious consequences. For example, black sufferers from psychosis living in white majority societies often delay formal treatment seeking due to social disadvantage and mistrust (Whaley, 2004). The consequence is increased likelihood of an emergency room admission with police and/or ambulance involvement, as symptoms have had time to worsen (Whitley, Kirmayer, & Jarvis, 2004).

Evaluation

Once Hana or her family decide to seek treatment, they may encounter professionals who are trained to work with discrete diagnostic categories reflecting Western scripts of mental illness. Disciplinary biases that come with clinical training include overlooking the bottom-up dimensional nature of many common forms of mental disorder in favor of top-down diagnostic categories (Haslam et al., 2012) and overemphasizing Western understandings. In addition, diagnoses are further shaped by clinicians' own cultural contexts. Cross-national differences in diagnoses emerge even when clinicians rate the same prerecorded targets. Despite some similarities driven by the Western-derived diagnostic instruments and manuals, clinicians from different countries see the same symptom reports and behavior as indicative of somewhat different symptoms, which in turn may point to different diagnoses (Katz, LeBars, Itil, Prilipko, & DeGiralamo, 1994; Nakane et al., 1988). For example, in one study, clinicians in Japan, China, and Korea saw the same videotaped interviews with patients. The resulting diagnoses

systematically differed by country, with Japanese clinicians emphasizing depressive and psychotic symptoms in their diagnosis, Chinese clinicians emphasizing anxiety symptoms, and Korean clinicians showing an intermediate pattern (Nakane et al., 1988).

Even more troubling, clinicians detect, interpret, and prioritize symptoms in ways that are informed by their cultural contexts' social representations, applying different diagnostic intuitions to patients from different cultural and ethnic groups. For example, American clinicians have a tendency to overdiagnose mentally ill African Americans with a highly stigmatizing diagnosis of schizophrenia relative to European Americans and Hispanic Americans, who are relatively more likely to receive diagnoses of bipolar disorder and major depression, respectively (Minsky, Vega, Miskimen, Gara, & Escobar, 2003; Pavkov, Lewis, & Lyons, 1989; Strakowski et al., 1995). The case of diagnoses applied to African Americans versus Hispanic Americans is particularly striking, as the former tend to report fewer psychotic symptoms than the latter but are more likely to receive a diagnosis that centers around such symptoms (Minsky et al., 2003). Although these differences are known to be due partly to differences in how patients describe their symptoms, they are also shaped by the ways in which clinicians apply diagnostic information to individual patients (Strakowski et al., 1997).

While unstated cultural assumptions can affect psychological assessment and diagnosis in any clinical encounter, such assumptions are less of an issue when they are shared, with seemingly little need to complicate matters by interrogating them. Yet clinicians increasingly work with patients who inhabit very different cultural worlds, and the power and influence of "Western science" means these unspoken assumptions are exported to contexts for which they are not well-suited (Kirmayer, 2006). We believe the idea of cultural scripts can be usefully applied to this conundrum. As a thought experiment, imagine that a friend has come from a medical appointment and you want to find out how it went. In answering your question, it would be odd if your friend went into detail about checking in or reading a magazine in the waiting room. Instead, this "physician visit" script is understood to be shared; *violations* of the script, such as a secretary listening to loud music, are much more noteworthy. A deviant cultural script shared by people inhabiting the same cultural context is exactly that: It is

shared, and understood as shared. Imagine now that you are visiting another country and pick up a minor infection. You have a medical visit that proceeds in a very different way: You cannot find a receptionist, initial assessments are carried out in a public waiting room, and the physician recommends unfamiliar herbal remedies. Confused, you ask a local to walk you through a typical visit to the physician's office. When we cannot assume a shared script, we communicate differently, assuming less and questioning more.

There is an important difference, then, between assessing something broadly shared, with implicit and inferred scripts, and assessing something that may not be shared. In the latter case, the scripts themselves need to be made explicit. Knowledge of how deviant cultural scripts work may help us to develop and improve assessment techniques that allow specific scripts to come into view. One sound approach is to start qualitatively. For example, DSM-5 now provides the Cultural Formulation Interview (CFI; American Psychiatric Association, 2013) as a first step for assessing presenting complaints, etiological beliefs, and history of help seeking. If Hana's clinical evaluation were to include the CFI, she would be asked how she and others in her local social world understand her symptoms, her cultural and religious identity, her concerns about whether cultural misunderstandings might interfere with her care, and so on. A broadly similar but more comprehensive assessment is provided by the McGill Illness Narrative Interview (MINI; Groleau et al., 2006), which is more commonly used for research. Such instruments can be valuable for eliciting and elaborating on unfamiliar cultural scripts.

Researchers and clinicians can augment these ethnographically informed instruments with psychometrically sound tools that systematically sample culturally relevant symptom domains. A major challenge is to identify a pool of symptom experiences that can simultaneously reflect local sociocultural worlds and retain some degree of meaning beyond these worlds. For example, in order to compare symptom presentations in China and Canada, Ryder and colleagues (2008) pooled items from both Chinese- and Western-designed symptom measures. In the absence of indigenous measures, an alternative approach is to employ a mixed-methods approach integrating qualitative and quantitative assessment tools. Rasmussen and colleagues (2015) used such an approach to develop a depression rating

scale for use in Haiti. Careful qualitative work identified the key symptoms and the specific idioms of distress, as conveyed by expressions in Haitian Creole, which informed development and psychometric evaluation of a quantitative instrument.

Whether one uses unstructured or structured methods, the challenge is to understand the ways in which a problematic script is situated in the matrix of intersubjectively understood norms about normality and deviance, health and illness. This is not necessarily an easy task for clinicians, especially in highly multicultural settings. Should Hana be fortunate enough to live in a metropolitan area with access to a cultural consultation service, her clinician would have the option of seeking an evaluation from a multidisciplinary team that includes translators, cultural experts, and social scientists, in addition to mental health professionals (Kirmayer, Rousseau, & Guzder, 2014). Although resource intensive, cultural consultation can help refine diagnosis, provide clinicians with guidance on potential interventions, and improve access to resources (a community group, an immigration lawyer, and etc.). Recent advances in telehealth, including cross-cultural applications, are a promising development for the many clinicians who do not work in urban cosmopolitan settings (Mucic, Hilty, & Yellowlees, 2016).

Preliminary research suggests that cultural consultation is highly valued by clinicians who are in a position to take advantage of it (Kirmayer, Groleau, Guzder, Blake, & Jarvis, 2003). Moreover, there is evidence that this approach can help to resolve diagnosis; in one study, as many as 49% of patients originally diagnosed as psychotic were reclassified with other, nonpsychotic disorders. The distinction between a psychotic and a nonpsychotic disorder is far from trivial here, pointing to different treatment interventions and different implications for stigma. When clients were recent migrants, the likelihood of such reclassification increased, suggesting that the approach helps to clarify cases in which cross-cultural misunderstandings of symptom presentations may be a particularly salient issue (Adeponle, Thombs, Jarvis, Groleau, & Kirmayer, 2012). For Hana, the result could be a much more appropriate treatment, a reduced risk of hospitalization, a quicker return to functioning, a different response within her family and community, and more.

Intervention

As Hana searches for explanations and help, she will potentially encounter healers from a variety of training backgrounds and professional identities, offering a wide range of treatments. While there is a well-developed literature in medical anthropology on traditional healers, as psychologists, we focus here on “Western” psychological treatments. Our model of how culture, mind, and brain interrelate has implications for how the process of treatment is understood. A psychiatrist might be drawn to a neurochemical explanation of suffering and thereby conclude that a neurochemical intervention is needed, whereas a psychologist might prefer psychological explanations and believe they point to psychotherapy. But with mounting evidence to show that pharmacological intervention affects intra- and interpersonal functioning, and that psychotherapies impact brain functioning (e.g., Knutson et al., 1998; Linden, 2006; Serretti et al., 2010), it is clear these interventions affect disorder in complex ways. We similarly expect culture-level interventions (e.g., efforts to lessen mental health stigma; Na et al., 2016) to influence psychological and neurological functioning, although research is comparatively scant. Conversely, exposure to mental disorder and the actual or perceived effects of available interventions can shape culture by shifting consensual norms about normality and abnormality (Pescosolido et al., 2010). Indeed, some key Western ideas, such as beliefs about the self and the importance of a robust self-esteem, are shaped by the discipline of psychology itself (e.g., Mruk, 2013).

Just as disorder can emerge via multiple etiological pathways and form self-generating and self-perpetuating loops, so too can interventions show effectiveness at different levels. Indeed, the “effectiveness” of a treatment can itself get pulled into looping patterns. A treatment approach widely endorsed—fitting the cultural script of an effective intervention—may be more believable to the client and delivered more confidently by the clinician. Research on common factors in treatment has demonstrated that believability and confidence increase effectiveness (Benedetti, 2008; Luborksy et al., 1999; Wampold, 2001). How can clinicians ensure that Hana is a willing and engaged participant in her treatment? If treatment works in part because it is a believable cultural ritual that can be compromised by

cultural misunderstandings or a shaky therapeutic alliance, matching clients to clinicians from the same cultural background may be warranted. Perhaps Hana will “buy into” treatment delivered by someone from her own cultural context. Indeed, for many years, the literature focused on the extent to which a match between the client’s and the clinician’s ethnic group improves treatment outcomes. In a series of three meta-analyses, Cabral and Smith (2011) demonstrated a moderately strong preference for a therapist from one’s own ethnic group, and a modest tendency to appraise same-group clinicians more positively. Surprisingly, there was no difference in actual clinical outcomes (see also Maramba & Nagayama Hall, 2002), which suggests that despite its intuitive appeal, matching alone is unlikely to improve outcomes for someone like Hana.

While the lack of treatment effects for ethnic matching may be due in part to pervasive methodological problems (Karlsson, 2005), there are deeper conceptual issues to contend with as well. Matching assumes (1) that clients and clinicians can be fairly easily categorized as belonging to a single ethnic or cultural group, and that (2) clinicians and clients thus categorized will share similar cultural worldviews. In part due to these concerns, the literature in recent years has shifted away from matching and toward adaptation of treatment approaches to meet the needs of specific groups. Examples of common adaptations include the use of familiar metaphors or acknowledgment of local explanatory models. A meta-analysis by Griner and Smith (2006) demonstrated a moderately strong effect size for such interventions, especially when delivered in the client’s first language, pointing to more fruitful directions for culturally competent care.

The work of Hinton and colleagues on neck-focused panic attack and posttraumatic symptomatology in Cambodians provides a particularly detailed example of a culturally adapted intervention. Recall that anxious people raised in traditional Cambodian cultural contexts can present with neck-focused panic attacks. These panic attacks can in part be understood through general CBT principles, including the links between anxiety, attention, and actual and perceived autonomic arousal (Bouton, Mineka, & Barlow, 2001; D. Clark, 1986). Yet these attacks can only be fully understood through a cultural lens: It is difficult to clinically engage with them without reference to Cambodian folk biology and illness representations. These attacks must be placed within the larger context of local socioemotional

norms and the history of suffering during Pol Pot's regime in the 1970s (Hinton et al., 2013; see also Etcheson, 2005). Drawing from both general CBT principles and this cultural model, the researchers have developed culturally adapted CBT (CA-CBT) for traumatized refugees and ethnic/minority patients (Hinton, Rivera, Hofmann, Barlow, & Otto, 2012). Specific modifications for Cambodians include the explicit presentation of, and reference to, the neck-focused panic attack model to patients, as well as the use of Buddhist imagery for mindfulness and loving-kindness meditation exercises.

Nevertheless, even the approach of matching clients to culturally adapted interventions has its limitations. It invites clinicians and researchers to essentialize cultural groups, treating them as more clearly defined and internally homogeneous than they really are. The more we subdivide, the more specific treatments we need to develop. Furthermore, there will always be people who complicate group-based treatment efforts, for example, people from less well-represented groups, or people who inhabit multiple cultural worlds (Leung & Koh, [Chapter 21](#), this volume). An important next step for researchers, then, is to extract general principles from careful attempts to develop culturally specific treatments, integrate these principles into flexible treatment protocols, and evaluate the efficacy of these approaches. If successful, the result would be intervention approaches that are at once culturally informed, flexible with regard to the individual client and his or her local social world, and grounded in the best available evidence.

In short, we believe the key is to focus on identifying generalizable ways of learning about a given person's specific cultural context and salient cultural scripts, coupled with generalizable ways of integrating this knowledge with evidence-based treatment principles. In addition to the CBT-based examples provided earlier, there is also evidence to support the cross-cultural efficacy of treatments with interpersonal, mindfulness, parent training, and acceptance-based components (e.g., Rosselló & Bernal, 1999; Rosselló, Bernal, & Rivera-Medina, 2008; Singla & Kumbakumba, 2015; Singla, Kumbabumba, & Aboud, 2015). Regardless of the specific approach, we contend that successful therapies work by encouraging the emergence of positive perturbations in a system that is otherwise looped to generate distress and impairment (Ryder & Chentsova-Dutton, 2015). A successful

treatment for Hana would therefore involve its own, more functional, loops. Careful attention to cultural context not only improves understanding of this client, but it also shows compassion and concern, helping to build a strong therapeutic alliance. The safety provided by this alliance encourages her to attempt a change, such as exposure to a feared situation—with the situation chosen according to both knowledge of learning principles and an understanding of Hana’s fears in cultural context. Success in facing this fear and experiencing the consequent changes builds confidence and promotes trust in the alliance, which opens the possibility of attempting more difficult changes. The hope is that these virtuous, upwardly spiraling loops spread to her life outside the clinic and become the primary engines of further change.

CONCLUDING REMARKS

Psychologists have been addressing issues at the intersection of culture and mental health for several decades now. By 1980, work in this area was already sufficient for one of the six volumes of the *Handbook of Cross-Cultural Psychology* to be dedicated to psychopathology (Triandis & Draguns, 1980). The decade that followed included numerous contributions, some in close contact with developments in adjacent fields, but many more focused on the aptitudes needed by clinicians and counselors to work in increasingly multicultural societies. This practical focus, along with an emphasis on American ethnoracial categories, may have come at a cost, however. A review in the late 1990s showed a dropping off in clinical contributions to a major culture and psychology journal, a change attributed to a lack of theoretical sophistication in these submissions (i.e., *Journal of Cross-Cultural Psychology*; P. Smith, Harb, Lonner, & van de Vijver, 2001).

Ironically, North American cultural psychology was at the same time undergoing a rebirth following the publication of seminal works by Shweder (1991), Markus and Kitayama (1991), and a little later by Cole (1998). This perspective encouraged analysis of specific cultural contexts, while promoting a promising theoretical idea—the mutual constitution of culture and mind. They encouraged researchers to consider people like Hana as culturally shaped shapers of their context, simultaneously reinforcing and being affected by its models of what it means to be healthy and sick (Markus

& Hamedani, [Chapter 1](#), and Miyamoto et al., [Chapter 12](#), this volume). At the same time, cultural psychologists were fully engaged with the mainstream of cognitive, developmental, and social psychology; they remained well-grounded in the theories, methods, and findings from these subdisciplines, while also challenging some of their long-standing ideas and backing these challenges up with data (e.g., Henrich, Heine, & Norenzayan, 2010). Cultural–clinical psychology should aim to follow a similar path. Mutual constitution of culture and mind (and brain), along with ideas such as “cultural scripts” and the methodological focus on “unpacking culture,” can provide a robust theoretical framework. Cultural–clinical psychology should then seek to bring its findings to the mainstream to influence clinical research, practice, and training.

We believe that there is a need and the time has arrived. With a broadly defined cultural psychology as its basic science, cultural–clinical psychology can make important contributions to our increasingly multicultural societies. Accreditation bodies for psychology training programs, internships, and licensure have responded to demographic changes by calling for the infusion of culture into every aspect of training—yet there is little clarity on how this should actually be done. Moreover, the rapidly growing influence of global mental health initiatives (Becker & Kleinman, 2013; Patel & Prince, 2010), often oriented around exporting clinical psychology approaches (e.g., CBT; Rahman, Malik, Sikander, Roberts, & Creed, 2008; see also Singla et al., 2017), suggests a need for scientist-practitioners who both understand these approaches and are thoroughly grounded in cultural psychology. Cultural–clinical psychology can help fill these gaps.

As we noted at the outset, clinical psychology has a number of contributions to make to cultural psychology. In building a transdisciplinary bridge to adjacent disciplines, moreover, cultural–clinical psychology can infuse cultural psychology with fresh ideas from cultural psychiatry and medical anthropology, which share a concern with the interconnectedness of culture, mind, and brain. Cultural–clinical psychology demands that we engage with cells, social structures, and everything in between, and that we find ways to think about the links between generalizable findings and idiosyncratic single cases like our hypothetical case of Hana. The suffering client, moreover, requires us to get beyond abstract discussions of these

difficulties and find ways to effectively address them in specific people with specific problems. While the precursors to cultural–clinical psychology have been around for decades, this important work has only just begun.

CHAPTER 15

Culture and Development

Heidi Keller

Development can be understood as an interface between culture and biology. Humans are predisposed with a universal repertoire of developmental propensities that are emphasized or suppressed depending on environmental affordances and constraints. Cultural models may be understood as reflections of environmental conditions that are synthesized as sociodemographic milieus. Cultural models are structured by two overarching dimensions: autonomy and relatedness. Autonomy and relatedness are both human needs but may differ in their meaning depending on the respective sociodemographic milieus. Two prototypical environments are characterized: Western middle-class families with an orientation toward psychological autonomy and psychological relatedness, and rural subsistence-based farming families in non-Western countries with an orientation toward hierarchical relatedness and action autonomy. The portrayal of socialization strategies that support these two cultural models focuses on infancy as the brain imprint period of human ontogeny. The developmental consequences of the different early experiences are exemplified with respect to the timing of developmental achievements, the developmental dynamics of precursors and consequences, and the phenotypes of developmental results (Gestalts).

Attachment theory is characterized as one example where universal validity is claimed based on information from only one cultural context: Western middle-class socialization. It is argued that this (common) practice poses serious ethical problems. The reconceptualization of development as multiple dynamic processes has important implications for theory and practice.

Accompanied by his spouse during his research on childhood among the Dusun in North Borneo, Williams reports: “We were faced daily with Dusun parents raising their children in ways that violated the basic beliefs by which we were raised. . . . We consistently checked our . . . exclamations of concern or disgust . . . and [resisted] the temptation to take a ‘dangerous’ object, such as a knife, from a toddler . . . knowing that in terms of the local culture, children are believed to die from accidents whether they play with knives or not and besides, as one Dusun father put it, ‘How can you learn to use a knife if you do not use it?’ (Williams, 1969).” (Lancy, 2016, p. 654)

The role of context and culture for development has been conceptualized in manifold ways over historical time. These views range from a pure maturational unfolding of a genetic blueprint to behavioristic conceptions of development as stimulus—response conditioning to epigenetics as altering gene activity without changing the DNA sequence. For a long time, scholars tried to disentangle how much context—culture and genes contribute to behavior and its development, and how this interaction operates. Today, there is a growing consensus that context—culture and biology are inextricably intertwined, so that the German evolutionary biologist Eckart Voland (1995) formulated that everything is 100% biological and 100% cultural. The early phase of ontogenetic development constitutes a special window for studying the interplay between the genetic endowment and environmental influences. In the following paragraphs the conception of human development as the cultural solution of universal developmental tasks is presented. Two different developmental pathways are reconstructed from cultural anthropological and psychological evidence, demonstrating that there is not one way to achieve healthy human development. There are also not just two ways. But knowledge about other cultural environments is scarce.

DEVELOPMENT AS AN ECOBIOCULTURAL PROJECT

The basis for all developmental processes is in the brain. Evolutionary pressures—especially with respect to cooperation and competition with other members of the social group as the driving force of the evolution of intelligence and cognition (Alexander, 1979; Geary & Flinn, 2001)—resulted in an enlarged brain as compared to other primates. However, due to bipedality, another selection advantage, the birth canal is limited in width.

In order to be able to pass the birth canal, human babies are born physically immature and physiologically preterm (Prechtl, 1984). The result is an enormous capacity for postnatal brain development. The infant brain is designed to be molded by environmental conditions (Thomas et al., 1997). The pace of human brain development begins prenatally and continues through the second year of postnatal life with enormous speed (Gould, 1977). By 6 months, the human brain weighs 50% of what it will weigh in adulthood and 75% at 2 years (Tanner, 1978). Neurophysiological research has thus indicated that the first 2–3 years of life may be characterized as a brain imprint period. Accordingly, the neonatal environment has major and lasting consequences for development (Storfer, 1999). The primacy of the earliest experiences sets the stage for brain and psychological development. Nevertheless, synapse formation (connections among neurons) continues throughout life in order to ensure plasticity. Learning is therefore the driving force of human development throughout the lifespan; however, learning is not equivalent with development (Bischof, 2008).

Brain development is driven especially by two processes: general (species typical) and unique (individual) processes. Experience-*expectant* processes are common to all members of the species and evolved as a neural preparation for assessing general information from the environment. The overproduction and trimming of synaptic connections between the nerve cells illustrate experience-*expectant* information storage. Experience-*dependent* information storage reflects learning and brain development unique to the individual. The neural basis of experience-dependent processes appears to involve the active formation of synaptic connections as a product of experience (Greenough, Black, & Wallace, 1987).

A large body of evidence supports the principle that cortical and subcortical networks are generated by a genetically programmed, initial overabundant production of synaptic connections, which is then followed by an environmentally driven process of competitive interaction to select those connections that are most effectively supported by environmental information. Individual experience is therefore the product of an ongoing reciprocal interaction between the environment and the brain (Nelson, 2005), and learning environmental information is the crucial motor of development.

However, babies do not record everything that is going on in their environment, nor is learning random. Learning is specific concerning the content that is to be learned and the timing of when it is learned. The interplay of content specificity and timing of learning can be regarded as outlining evolved “epigenetic rules” (Wilson, 1975) or “central tendencies” (MacDonald, 1988) that direct attention to specific (environmental) cues at specific times. The acquisition of specific information during specific time windows allows “easy learning” (Boyd & Richerson, 1985; Draper & Harpending, 1988). For example, language learning, and learning several languages at the same time, is easy early in life and becomes more and more demanding with increasing age. The specification of content and timing of learning embodies developmental tasks.

Developmental tasks (see, e.g., Bischof, 2008; Erikson, 1968; Havighurst, 1972) represent topics or themes that have evolved during the history of humankind in order to solve adaptive problems. The specific solution of earlier adaptive problems prepares pathways for the solution of later developmental tasks. Thus, developmental pathways are organized in meaningful sequences. However, development is not deterministic in the sense that the early patterns prompt only one particular set of later consequences. It is obvious that along developmental pathways, a multiplicity of influences shape developmental outcomes. And human plasticity allows for modification, compensation, and restructuring at any time of development. Nevertheless, the development of continuity is easier than that of discontinuity, and most individuals experience coherence and consistency throughout their biographies (Keller, 1991, 2007). Coherence and consistency, however, do not imply a universal, trait-like organization of the human psyche. Coherence and consistency may also be experienced in situational fluid mindsets (see Morelli & Rothbaum, 2007, for a discussion of different types of coherence).

This conception of development combines a causal array of influences with a co-constructive mode. Since experiences are individually constructed and appropriated, the active role of the developing individual and the contextual properties form one system. Thus, behavioral phenotypes are generated in context. Developmental pathways may be understood as template models proposing life-course trajectories with flexibility for individual variability (Jensen, 2011, 2015).

CONTEXTS OF DEVELOPMENT

The agricultural Dusun in North Borneo, who let their children play with knives, obviously live in a different environment than a child from a middle-class family in a Western metropolis. The physical/material structure is the starting point for conceptualizing environmental influences and contexts of development. The landscape, with its climate and the seasonal conditions, shapes the development of population parameters, most importantly fertility and mortality as functional units; that is, high mortality is associated with high fertility and decreasing mortality rates with decreasing fertility rates (Chisholm, 1999; Volland, Dunbar, Engel, & Stephan, 1997; Wilson & Daly, 1997). Settlement patterns, household composition, and social structure are contingent on these parameters, which are reflected in norms, values, and beliefs, as well as behavioral regulations. These processes always have to be situated into historical, sociopolitical contexts (Bronfenbrenner, 1977; Cole, 2002; Marey-Sarwan, Keller, & Otto, 2016; Vicedo, 2013). Thus, culture is constructed and co-constructed in a dynamic process along these different dimensions. It may be regarded as a representation of contextual information that is created individually during ontogeny; however, individuals who live in similar environments also share norms, values, and behavioral conceptions to a large extent. Culture therefore reflects the demands of ecocultural environments (Berry, 1976; Hewlett & Lamb, 2002; Keller, 2007; LeVine, 1974, 1988; Talhelm & Oishi, [Chapter 4](#), this volume; Weisner, 1987; Whiting, 1963) and defines it as the primary mode of human adaptation (Greenfield & Keller, 2004; Keller, 2007; Rogoff, 2003).

In order to understand the culturally shaped human psychology, it is therefore crucial to contextualize empirical studies in ethnographic accounts of the respective environment (Hay, 2016; Gaskins et al., 2017). Sociodemographic milieus can be regarded as a proxy for environmental ethnographies (Keller, 2007; Keller & Kärtner, 2013). Sociodemographic milieus are formed by the interplay of several dimensions that are driven by the degree of formal education. “Formal education” means school education, which is modeled more or less after the Western school system, no matter where the schools are located. Formal schooling is situated in classrooms, with trained adult teachers and an explicit educational agenda. It therefore differs substantially from nonformal or incidental education, which is

situated in everyday routines and practices and aimed at the acquisition of local knowledge.¹

The degree of formal education is related to the fertility rate of individuals on a worldwide scale (Cochrane, 1979). The higher the degree of formal education, the later the birth of the first child and the lower the number of offspring in general. The acquisition of higher formal education postpones income-generating activities as a basis of family foundation and procreation. The degree of formal education also influences the household composition and therefore the definition of family. More formally educated individuals live predominantly in two-generation households and nuclear families. Less formally educated individuals tend to live in multigenerational households and family clans. The family organization reflects, moreover, the economic base of the individual and family. On average, more educated individuals tend to live in more prosperous and economically affluent milieus than formally less educated families, who may be exposed to more existential struggles in this respect. Formal education, age at the first birth, number of children in the household, and household composition therefore form sociodemographic milieus. Psychological research tends to treat these parameters as variables, controlling their individual effects statistically. The argument that is put forward here is that their effect is cumulative and interactive, in that they create contexts (i.e., milieus with particular affordances and constraints). In order to regulate behavior within these contexts, norms, values, beliefs, and behavioral conventions that have developed are organized in cultural models. These models are dynamic and underlie processes of change, along with environmental changes, so that culture is transmitted, created and co-created between and across generations (Moscovici, 1984; Keller, 2016).

This conception definitely excludes countries or societies as units of cultural or cross-cultural analysis. Countries host multiple sociodemographic pockets that necessitate different adaptive patterns and therefore different cultures. What is usually labeled as “intracultural variance” can therefore be regarded as the coexistence of multiple cultures. In this view, also, representativeness of samples would mask or distort cultural differences.

The existing psychological knowledge is mainly based on one particular ecocultural context: that of the Western middle class. Formal education is

usually highly coincident with late parenthood, fewer offspring, and individualized parental investment in each child (Keller & Chasiotis, 2005; Keller & Kärtner, 2013; Kraus, Callaghan, & Ondish, [Chapter 27](#), this volume). Children are primarily raised in nuclear families that value children for the psychological rewards they bring. They are not primarily economic assets to their families since they usually do not contribute to family income (Kağitçibaşı, 1996). On the contrary, older generations support the younger ones, so that often grandparents also participate economically in the education and settlement of their grandchildren. Life is situated in the anonymous, large-scale reality of Western postindustrialized and knowledge societies (Keller, 2003; Keller, Zach, & Abels, 2005c). This context represents a very small part of the world's population, presumably less than 5%. Research results originating from this population, however, are generalized to the world's population in general. This practice has come under serious criticism during the last few years. Jeffrey Arnett (2008) published an article in *American Psychologist* with the title "The Neglected 95%." The article in *Behavioral and Brain Sciences* by Henrich, Heine, and Norenzayan (2010) has attracted broad attention, with the conclusion that Western psychology is WEIRD (White, Educated, Industrialized, Rich, Democratic) and highly unrepresentative of the world's population and its psychologies. Generalizing Western middle-class psychology to non-WEIRD contexts poses substantial ethical problems (Morelli et al., 2017, 2018a, 2018b).

Obviously there are other ecocultural contexts on this planet that are largely understudied. One context that is particularly relevant for our discussion refers to the dense social network of traditional farming village communities. Economy is usually subsistence-based, with little economic diversity among multigenerational households and clans. The population is small scale, with person-to-person interactions as the prevalent social mode. Formal education, if at all available, is basic. Lifestyle is characterized by hierarchical family systems based on age and gender, and communal work. Reproduction starts early, with more children and less individualized parental investment (Keller, 2003; Keller & Kärtner, 2013). The value of children to the family is economic and psychological (Kağitçibaşı, 1996). This ecocultural context is estimated to represent around 30–40% of the world's population. Moreover, it is the environment from which modern city

life has evolved (LeVine & LeVine, 2016), and it defines the background of most migrants to Western societies.

These two types of environments and their respective cultural models may be regarded as prototypes from which variations and combinations arise (Keller, 2003, 2007). One hybrid type that has received quite a bit of attention in the past is urban middle-class individuals/families from non-Western countries. They have an equally high formal education as their Western middle-class peers, yet they occupy an intermediate position between the Western middle-class and the rural farming life with respect to age at first birth, number of children, and household organization (Kağitcibaş, 2007; Keller, 2007; Keller & Kärtner, 2013). Mode of subsistence also has an impact on cultural patterns of adaptation, as variation from the farmer's model has been reported with respect to foragers (Hewlett, 2004), nomadic herders (Casimir, 2010), and fishermen (Uskul, Kitayama, & Nisbett, 2008). Nevertheless, they all differ substantially from the Western middle-class cultural model. However, it is important to stress that the two prototypes do not represent a dichotomy. Moreover, there may be other cultural models that exist but are unknown to date.

CULTURAL MODELS AS ORGANIZERS OF DEVELOPMENT

Children's learning environments are structured according to the implicit and explicit scripts of the prevalent cultural models. These models can be assumed to be organized by two overarching dimensions that are basic human needs and cultural conceptions at the same time: autonomy and relatedness. All humans are individual persons with a need for autonomy and members of social communities with a need of relatedness (Angyal, 1951; Bakan, 1966; Deci & Ryan, 1991). Autonomy and relatedness are themes of universal importance, embodied in social practices that are normative and consensual in particular environments (D'Andrade, 1995; Kim & Lawrie, [Chapter 10](#), this volume). Therefore, the definition of autonomy and relatedness must vary in line with sociodemographic milieus.

Being a competent member of the Western middle-class world is based in a cultural model promoting individuality, self-determination, and

(individual) freedom of choice. These values pertain to the psychological dimensions of autonomy in terms of independent mental states, with a focus on individual preferences, self-maximization, and self-fulfillment, which have been conceptualized as psychological autonomy (Keller, 2012; Keller & Kärtner, 2013). Psychological autonomy enacts a self-reflective way of being centering on the exploration and reflective awareness of personal desires, wishes, and intentions. This conception represents what is usually defined as autonomy or agency in most of the present literature. This mode of defining autonomy has consequences for the definition of “relatedness,” which in this worldview must mean that separate, self-contained individuals establish self-selected relations with others that are defined and negotiated from the point of view of individual psychological autonomy. Thus, the conception of psychological autonomy organizes the understanding of relatedness. This does not imply that relatedness is less important for the psychological functioning and well-being of the individual than autonomy (Keller & Kärtner, 2013). Defining oneself as an independent mental agent prompts the understanding of others as equally independent mental agents, with individual theories of mind. It forms the basis of functioning in a complex world that is characterized by daily multiple encounters with strangers, uncertainty, and unpredictability of life circumstances related to technological and societal change, necessitating mobility in a competitive labor force. Self-centeredness is therefore crucial in order to define and establish one’s own position in society. Due to the organizing quality of psychological autonomy for this cultural model, we refer to it as the “cultural model of psychological autonomy.”

However, anthropologists have described conceptions of the mind that do not focus on individual mental states as discussed in the Western literature (e.g., Duranti, 2008). For example, the South Sea Kaluli rainforest dwellers assert that they do not know what others think or feel, or what is in the minds of others. Their conception of mind has been described as expressing opacity (Schieffelin & Ochs, 1986). Daniel Everett (2009, 2014) observed a principle of “immediacy of experience” that excludes reference to experiences beyond the here and now in the Amazonian Piraha Indians. Barrett and colleagues (2016) reported that individual intentions were much less evaluated for moral judgment in eight different small-scale societies. Nevertheless, it cannot be denied that small-scale farmers, hunter-gatherers,

horticulturists, or fishermen exert agency and autonomy in their lives; otherwise, they could not survive in demanding environments without any external regulation or support. In these environments, “action autonomy” is crucial, representing the person’s capacity to act individually in a self-responsible and self-controlled way in the service of daily responsibilities. Action autonomy is therefore part of a cultural model promoting interconnectedness with others in a system of “hierarchical relatedness,” which implies including others within the boundaries of the self, so that relationships with others become the central feature of the self-concept. This implies valuing cooperation, and conformity, obligation, and respect as basic motifs of social regulation. Due to the organizing quality of hierarchical relatedness for this cultural model, we refer to it as the “cultural model of hierarchical relatedness.”

Although the prototypes are defined through stable combinations of the respective modes of autonomy and relatedness (psychological autonomy and psychological relatedness on the one hand, and hierarchical relatedness and action autonomy on the other), multiple other combinations are possible—for example, non-Western highly educated urban families combine psychological autonomy in some segments of their lives with hierarchical relatedness in other segments of their lives (Keller, 2007; Keller & Kärtner, 2013).

In the following paragraphs, we briefly characterize the Western middle-class and the rural farming pathway. The reconstruction of these pathways is empirically based. A special emphasis is being put on the stage of infancy as the brain imprint period in which earlier influences are fundamental organizers of later influences and experiences.

INFANCY ACROSS CULTURES

Infancy constitutes a separate life stage in all primates between birth and about 2 years of age and is followed by an extended and dependent childhood phase. In other mammals, infancy ends with the cessation of weaning and is followed by the juvenile period, in which the young are no longer dependent on the parents for survival but are not yet sexually mature. The importance of the prolonged infancy and childhood period for humans

is that they need a preparatory period to be able to adapt to the complex social environment that constitutes their niche. Learning through participation in everyday activities is the major avenue for the acquisition of local cultural scripts (Gaskins, 2014; Rogoff, 2003). Infants are active and selective perceivers and information processors. They communicate needs and wishes, and express moods and emotions. Thus, already infants are able to influence and control their environment. Depending on infants' reactions to contextual information and their motivation to engage in different areas of expertise, they transform cultural processes into individual achievements (Lancy, Bock, & Gaskins, 2010).

This view of infancy is rather recent. The prevalent view of infancy for much of the 20th century had been that of a "blooming buzzing confusion" that William James (1890) had described. Extensive ethological long-term observations documenting impressive social-cognitive competencies changed this image, so that the competent infant was born during the 1950s–1960s. Joy Osofsky published the first edition of the *Handbook of Infant Development* in 1979. Infancy is especially pertinent to illustrate the interplay between universal predispositions and cultural influences. As a species, humans are biologically primed to acquire, create, and transmit culture. Therefore, infants are equipped with a universal repertoire of behavioral predispositions from which the culture selects, emphasizes, suppresses, and reinforces (Greenfield, 2002; Keller, 2002). It can therefore be said that infancy constitutes a lens through which to understand critical cultural decisions and orientations (Gottlieb, 2004). Infancy has attracted the interest of cultural psychologists and anthropologists for a long time. Therefore, more information on infancy is available from diverse cultural environments than for other life stages.

In the following, we discuss infants' learning environments derived from the two cultural models.² The model of psychological autonomy informs the foundation of a self- concept as self-contained, competitive, separate, unique, self-reliant, having an inner sense of owning opinions and being assertive (Markus & Kitayama, 1994). The model of psychological autonomy focuses on mental states and personal traits supporting self-enhancement, self-expression, and self-maximization. The self is defined as "essentialist," which means to have a timeless core identity that is consistent across situations (Flores, Teuchner, & Chandler, 2004).

The model of hierarchical relatedness informs the development of the self-concept as part of a social system, mainly the family. The self-construal is context sensitive and fluid. Individuals strive for harmony and accept hierarchy and role-based authority. Fulfilling obligations is a source of life satisfaction and well-being (Keller, 2013; Morelli & Rothbaum, 2007). The different conceptions of the self are represented in socialization goals, parenting ethnotheories, and behavioral strategies.

THE PATHWAY TOWARD PSYCHOLOGICAL AUTONOMY

The social world of the infant is mainly dyadic. The mother is usually the major social partner for the infant during the first years of life. Fathers in nuclear families also participate in child care but are rarely the main caregiver. Cultural messages are embodied in verbal and nonverbal conversations, and enacted in contexts that are created for infants, providing child-centered social and physical experiences (“neontocracy”; Lancy, 2008). In this model, children learn first about themselves before they learn about others. The major cultural messages that infants receive are individuality, mental agency, and self-worth/self-enhancement. In the following paragraphs, we highlight the experiences that transmit these conceptions.

Individuality

Caregivers interact exclusively with the baby, directing their full attention especially to the face. The communication is mainly enacted in this distal mode (looking, hearing) with verbal/vocal exchanges, smiling, and other facial expressive behaviors. There is little body contact and motor stimulation, which allows baby and caretaker to concentrate fully on the distal exchange. Babies from Western middle-class families experience prompt reactions to their distal signals when mothers or (a few) other caregivers react intuitively within a time interval of maximally 1 second following the infant signal (Papousek & Papousek, 1991). This interactional mechanism of contingency experiences supports the perception of

separateness (Keller, 2007). With the help of an equally inborn contingency detection mechanism, infants notice the relationship between their signals and the responses, which allows them to perceive themselves as controlling others' behaviors (cf. mental agency). Prompt responsiveness is part of the definition of maternal sensitivity (i.e., prompt, consistent, and adequate responses to infants' signals are considered to be the essence of quality caregiving during the first year of life, according to attachment theory; Ainsworth, Blehar, Waters, & Wall, 1978).

On the other hand, infants spend an equal amount of time on their own, as they are involved in these intensive social exchanges, about 30% of their waking times during a normal day (Keller, 2016). The remaining time they may be in the vicinity of others without experiencing exclusive attention. Mothers believe that it is important for infants to learn early to spend time on their own and not always be dependent on others. Toys play an important role in this strategy, since they may distract the baby from socializing and replace the mother or others. Parents accept that babies develop relationships with objects such as security blankets or pet toys, since this is assumed to support their social independence. Being overly dependent on others is regarded lifelong as a risk factor for development and well-being.

The same attitude is also expressed in parents' endeavors to enable young babies to sleep alone in their own bed or even in their own room. Also, pediatricians promote babies sleeping independently and assume a benchmark of about 3 months of age, when a baby should be able to sleep independently through the night. Being able to spend time alone is considered to be the basis of the development of identity and therefore a conception of self as an independent agent (Keller, 2016).

Individuality is further expressed during the conversations that refer to the particular child's past and future. Mothers explain to the baby during the first weeks of life what he or she did yesterday and what he or she will do tomorrow, thus prompting an individual autobiographical identity (Keller, 2007). Babies are addressed by their names or individualized nicknames, including diminutive forms of their names.

The expression of positive emotionality is another asset of individuality (Shweder & Bourne, 1984). Emotions are regarded as a direct expression of the self and an affirmation of the importance of the individual (Markus &

Kitayama, 1994). Babies are encouraged from birth on to smile and to utter positive vocalizations in order to express happiness. Mothers' conversations with their babies center a great deal on the fun the baby is supposed to have and the joy of life the baby is expressing with the smiles and the positive vocalizations (Tsai & Clobert, [Chapter 11](#), this volume). Accordingly, babies who are not in a good mood and do not smile as their mothers' wish leave mothers helpless, so that they may even change to a more demanding conversation style, informing the baby that he or she should smile, since there is no reason not to do so. Otherwise, questions have the adult conversational format of dialogic (quasi) partnership, leaving the space to answer with whatever conversational contributions (smile, vocalization, change of gaze direction, mimic, gestural signs). This is another indication of individuality, since the baby's contribution, the assumed opinion of the baby as a separate and independent conversational partner, is requested and respected (see also mental agency).

Mental Agency

Mental agency is attributed to the baby during conversational exchanges. In an ongoing stream of verbal/vocal messages, mothers and others refer to the inner states of the baby ("Are you bored?"), needs ("Are you tired?"), wishes ("Do you want to play alone?"), and preferences ("Do you want Mommy to read your book?"). Mothers offer choices between themselves and toys (e.g., she is watching her toys; this is more interesting than Mommy; this is OK; she can do this). Mothers are interpreters of infants' perceptions and interpret the world for them. Mind-mindedness is assumed to be even more important than sensitivity; Elisabeth Meins and colleagues (2003) argued that they rethought the concept of sensitivity and came to concentrate on the maternal competence to read correctly the mental states behind the behaviors. Babies should be seen and treated as being intentional agents (Meins et al., 2003). Also Fonagy, Gergely, Jurist, and Target (2002) concentrated on mentalization as the mental activity that allows babies to perceive and interpret human behavior as intentional (mental) states—needs, wishes, beliefs, goals, intentions, causes—that are important for the development of secure attachment relationships.

The language register that Western middle-class parents utilize in interactional situations is generally voluminous and elaborate. Nevertheless, they also follow intuitive adaptations to infants' information-processing capacity with "motherese" or babytalk, which represents intuitive components of the parenting repertoire. They talk slowly with many repetitions, a high pitch, and increased frequency. They structure the conversations as quasi-dialogues that attribute to the infant an equal role and equal importance during the conversational flow (Keller, 2003; Keller et al., 2004a; Demuth, 2008).

Self-Worth

Self-worth and self-enhancement are transmitted indirectly as well as directly. The exclusive dyadic attunement between caregiver and infant is an indirect statement of the infant's value because of the investment of time and energy. Direct expressions of the infant's worth are embodied in continuous praising. Mothers and others praise the infant constantly during interactional conversations for his or her developmental achievements, how big he or she already is, and how he or she is strong, cute, and pretty. Another domain of praise is the developmental progress, that the infant can already talk so nicely (when vocalizing), that his or her smile is so big, that he or she is doing whatever he or she does so well. Addressing her 3-year-old son, a middle-class mother from Los Angeles claims, "You're the tallest boy in the world, huh?" Also Miller, Wang, Sandel, and Cho (2002) point to the importance European American mothers place on fostering high self-esteem. They conclude that the provision of love, affection, and praise is an appreciation of the child's inherent worth.

Of course, individuality, mental agency, and self-worth are not separate messages but are interlinked with each other. Therefore, the cultural messages in these interactional exchanges are manifold and support each other, so that consistent patterns of cultural meaning are emerging. Quinn and Holland (1987, p. 10) proposed the conception of "temacity," which captures a similar idea. Temacity describes conceptions that are introduced in different areas with different functions. This multifunctionality creates consistency, reinforcing the cultural messages that the child receives.

Although infants do not understand the semantic content of these messages, the intonation, patterning, and direction of the messages carry cultural meaning as well. Kathleen Wermke and collaborators (2013) have demonstrated with spectral analysis that babies' cries during the first hours of life already reflect cultural communication patterns. For example, French babies cry with a rising melody, as represented, for example, in the word *maman* (emphasis on the second syllable), whereas German babies cry with a falling melody as represented in the word *mama* (emphasis on the first syllable) (Wermke, 2011). Three-month-old Nso babies already use clicks in their vocalizations (Wermke et al., 2013). Thus, the verbal/vocal environment of the baby starts prenatally to shape and prompt language development.

Naomi Quinn (2005) talks about “predispositional priming” in this respect, which refers to the social experiences of prelinguistic children as preparatory lessons for later learning. These lessons are taught with “experiential constancy” when experiences are regularly repeated in the same consistent framework. Culturally shaped “emotional appraisal” such as praising and cherishing the child in the case of the Western middle-class baby, intensifies the child's learning experience, and the child's behaviors are approved through “evaluation” (Quinn, 2005; see also Röttger-Rössler, Scheidecker, Funk, & Holodynski, 2015). Confirmation and evaluation of the child's behavior is a constituent part of Western middle-class parents' elaborative conversational styles over the first years of life.

Western middle-class infants acquire their basic conceptions of the self and the self-in-relationship within this learning environment. The overarching principle of these learning experiences is that infants learn to see the world from a self-centered perspective.

THE PATHWAY TOWARD HIERARCHICAL RELATEDNESS

Infants from rural, subsistence-based farming communities in the non-Western world are mostly silent participants in family life and chores. They are embedded in a dense multigenerational social network with several caregivers, often children. Cultural messages are embodied in verbal and

nonverbal conversations within the multiple caregiving system with multiparty interactions. Infants therefore learn first about others and the social system before they learn about themselves. The major cultural messages that infants receive in this social environment are community/communality, obligation, and modesty/respect. In the following, we highlight the experiences that transmit these messages.

Community/Communality

Infants are attached to the backs, hips, or laps of others who are involved in their daily duties. Yet infants are not neglected at the expense of other occupations; caregivers are equally attentive to different targets. This kind of distributed attention has been described for different non-Western communities as co-occurring care or shared attention (Saraswathi & Pai, 1997). Thus, infants are almost never the center of attention, but they almost never alone. The preferred mode of caregiving is proximal: Body contact, and motor stimulation are the prevalent parenting systems besides primary care. Contingency is also an important interactional mechanism in this parenting strategy, yet it is displayed bodily. Prompt reactions to bodily signals occur, for example, as posture changes or adaptations (Chapin, 2013).

Parenting behaviors are often anticipatory before the infant has explicitly expressed a need, for example, through crying (Morelli, 2015). Thus, the development of a separate identity is not the primary concern, but the development of fusion and belongingness. Anticipatory responsiveness is a means to blur the ego boundaries (Rothbaum, Pott, Azuma, Miyake, & Weisz, 2000a; Rothbaum, Weisz, Pott, Miyake, & Morelli, 2000b; Morelli & Rothbaum, 2007) in the service of the development of a communal identity.

Infants are generally not exposed to one primary adult caregiver to whom they should develop this special and significant emotional bond to make this relationship unique. Multiple caregiving arrangements transmit relational patterns, in which individuals may replace and supplement each other. A common pattern is that during the first 2 or 3 years, the mother is nursing the baby, but social stimulation is provided by other caregivers, mainly other children (e.g., Scheidecker, 2017). Communal caregiving

fosters the sense of belonging as opposed to individualized and nontransferrable bonds.

It is probably the most obvious difference in caregiving patterns across cultures that the exclusive dyadic organization of caregiving between one adult caregiver and one infant is the exception rather than the normal case for humans in general. From an evolutionary point of view, anthropologist Sarah Hrdy (1999) has convincingly argued that humankind would not have survived if mothers had been infants' sole caretakers. She proposed a cooperative breeding model (Hrdy, 1999, 2009) as a social system in which nonparental members of a social group—"alloparents"—help to support offspring who are not their direct biological descendants. Accordingly, we find patterns of alloparenting in many cultural environments (for a summary, see Lancy, 2008; Otto & Keller, 2014; LeVine & LeVine, 2016; Quinn & Mageo, 2013). For example, among the Efe of Zaire, newborns are passed between women who collectively hold, carry, and nurse the infant. At the age of 6 weeks, Efe infants spend more time with other persons than with their biological mothers (Tronick, Morelli, & Ivey, 1992). Similarly, Gottlieb (2004, 2014) has presented extensive evidence that after birth, Beng babies from the Ivory Coast typically see the mother, a grandmother, often an aunt, and perhaps one or two other female kin. "The newborn's social circle widens dramatically almost immediately following the birth. . . . Within about an hour, a long line forms outside the door of the birthing room" (Gottlieb, 2014, p. 191). Courtney Meehan (2005) reports that among the Aka tropical forest foragers, who reside in the Congo Basin rainforest, children are raised in cooperative child-rearing systems. Infants and young children have approximately 20 caregivers interacting with them on a daily basis. Aka mothers remain primary caregivers in infancy, but maternal care significantly decreases after the child's first year of life. Alloparenting and multiple caregiving have also been documented in many other parts of the globe, such as families in an Indian temple town (e.g., Seymour, 2004; Sharma and LeVine, 1998), Brazilian Piraha Indians (Everett, 2014), and Chilean Mapuche (Murray, 2013). Yet, in a wide variety of arrangements, the mother plays no special role at all, for some time, or she is just one caregiver among others. In any case, children from age 3 to 4 on are reliable and responsible caretakers of younger ones (Keller & Chaudary, 2017). The anthropologist Gabriel Scheidecker has documented a remarkable portrait

of children's social matrix in villages in the south of Madagascar. He assessed the social encounters and experiences of children during different age spans, with multiple short-term observations over an extended period of time ("spot observations"). In this community, the mother is the primary caretaker during the infant's first 2 years of life, with a proximal parenting style. However from birth on, other caretakers play an important role providing the infant with social experiences. Eye contact and smiling with the mother hardly occurred at all. From about 2 years of age on, the mother basically disappears from the social matrix of the child, as well as that of other adult caregivers. Same-age peers constitute the significant social network in which major socialization processes are occurring (Scheidecker, 2017). Also at night infants co-sleep with others, depending on the general caretaking system, with the mother or with other household members (Shweder, Jensen, & Goldstein, 1995).

Husbands and fathers in farming villages, who lack formal education, usually sleep separately; co-sleeping of couples becomes more popular with increasing formal education and nuclear family organization (Yovsi & Keller, 2007). The role of fathers is also restricted due to postpartum leaves of sometimes several months to the family of origin and the cultural understanding that fathers are primarily providers of material and economic security in many communities (Lamm & Keller, 2012).

Obligation

Hierarchical relatedness is based on the acceptance of roles and norms. Babies are addressed in their roles as children, who are supposed to behave in a socially appropriate manner. Children may also be addressed in their social-spiritual roles and positions, such as when Nso farmer children are approached as *faay* (traditional title) since babies are the connection to the ancestral world (Nsamenang, 1992). The lifespan is not conceived of as linear from birth to death but as a circle linking generations together (Dasen, 2003) in which new members are inserted in the chain of ancestry. This intergenerational commitment is based on a system of obligations.

Infants are conceived of as apprentices who, on the one hand, are guided and trained (Yovsi, 2004; Yovsi, Kärtner, Keller, & Lohaus, 2009), and on the

other, are expected to be self-reliant, responsible, and obliged learners through imitation and observation (Lancy, 2016; Gaskins, 2014). This child-rearing model is based on hierarchy and authority. Conversations are directive (Chao, 1995), characterized by commands and instructions, with seniors (mother or other caregivers) taking a leading role. Children follow the lead of the caregiver and have a confirmatory role rather than bringing in their own initiatives. David Lancy (2008) names this socialization model “gerotocracy,” which places a high value on the social context, moral rectitude, and behavioral consequences (Miller, Jung, & Mintz, 1996; Mullen & Yi, 1995; Wang, Leichtman, & Davies, 2000).

Modesty/Respect

Respect for elders and obedience are central mechanisms that are enacted in the daily experiences of infants from birth on. Children have to learn that they must fit in and not stick out (Schröder, Kärtner, Keller, & Chaudhary, 2012). Children comply with the demands and requests of their social surroundings (Keller et al., 2004b). Emotions are viewed as disruptive and are expected to be controlled (Wang, 2001; Wang et al., 2000; cf. Bond, 1991; Chao, 1995). Children are not praised but are instructed with moral codes. Critiquing and shaming are common mechanisms even with babies. If they seem to do something that their caregivers do not want to see, they are scolded as bad children. Robert LeVine (2004, 2014) found that Kenyan Gusii mothers address their children with commands and threats rather than praise or interrogatives.

These principles set the stage for a developmental pathway that is oriented toward hierarchical relatedness as the leading principle, which is correlated with a definition of “autonomy” as action autonomy. Development is situated in the present, the here and now. Generally, the emphasis is on responsible acting and does not reflect the individual perspective.

Babies from rural non-Western farming families acquire their conception of community and a relational definition of the self within this learning environment. The overarching principle of these learning

experiences is that infants learn to perceive the world through a communal perspective.

Different cultural models help us understand the complexity of cross-cultural variability and help organize this variability in an ecocultural framework. It is, however, important to stress, that the cultural models of psychological autonomy and hierarchical relatedness do not represent binary oppositions since the one is not the opposite of the other. The perception of what is contradictory or consistent is also dependent on the cultural worldview. What may be considered a contradiction or even incompatible in one worldview may not pose a problem at all for an individual with another worldview, due to different conceptions of coherence.

Multiple combinations of the dimensions of cultural models generate various possible cultural models (Keller, 2007). Although different authors have emphasized the independence of autonomy and relatedness (Kağitçibaşı, 2007; Keller, 2007; Keller & Kärtner, 2013), the concepts are still often misunderstood as bipolar and dichotomous (e.g., Branco, 2003; Neff, 2003; for a discussion, see Cole & Packer, 2016).

THE LOGIC OF DEVELOPMENTAL PATHWAYS

The considerations presented so far have important implications for the consequent developmental processes that follow the logic of the cultural foundations laid during the first year. Specifically, the following dimensions are important: the timing of developmental achievements, the dynamics of developmental processes and the developmental Gestalts (i.e., the phenotypic appearance) (Keller & Kärtner, 2013). We highlight these three dimensions in the following paragraphs.

Timing of Developmental Achievements

One of the basic assumptions in cross-cultural developmental psychology is that cultural priorities accelerate the development of particular domains more than others, the “cultural precocity” assumption (LeVine et al., 1994).

Cultural priorities are embodied in socialization strategies emphasizing particular and specific developmental domains. These emphases have important implications for the onset of developmental processes, the associated developmental trajectories, and the sequence of specific developmental achievements within a specific domain.

The stunning cultural differences regarding the achievement of gross motor behaviors during the first year of life, especially between sub-Saharan and Western middle-class infants (“the motor precocity” of the sub-Saharan infant), have attracted the attention of cultural anthropologists and psychologists for quite some time (see Lohaus et al., 2011; Super & Harkness, 2015). After some unsuccessful attempts to relate these differences to genetic endowment, socialization practices were identified that support gross motor behaviors differently. Sub-Saharan African infants are encouraged through specific practices, mainly holding the infants in an upright position and moving them vertically up and down. This practice has been observed and documented in villagers such as the Kipsigis and !Kung San (Harkness & Super, 2001), the Gusii (LeVine & LeVine, 1963), the Wolof (Faladé, 1960), the Bambara (Bril & Sabatier, 1986), and the Nso (Keller, Yovsi, & Völker, 2002). These social interactional practices are supplemented through specific training practices—for example, training the sitting position by using holes or containers or training walking with the use of handmade wooden walkers or placing infants between handrails made from bamboo (Konner, 1977; Super, 1976; Keller et al., 2002).

Systematic comparisons of individual gross motor competences (e.g., as defined in the Bayley Scales of Infant Development; Bayley, 1969) of German middle-class infants and Nso infants from farming families revealed the interesting result that 6-month-old Nso infants exceeded German infants in sitting and standing, whereas German 6-month-olds performed better at rolling from their backs onto their sides and stomachs, and at grasping their feet with their hands (Lohaus et al., 2011). This difference obviously directly reflects the experiences of German infants, who spend substantial parts of the day lying, mainly on their backs, and those of Nso infants, who receive regular motor stimulation and training in an upright position. These different experiences reflect the different child care philosophies: Nso families perceive motor stimulation as a crucial part of an infant’s early development. It is important for the Nso community that

motor independence allow children to be helpers in the family as early as possible. German middle-class families, on the other hand, think that motor training is dangerous for children's development. Also, pediatricians do not want children to sit or stand too early. Each child is assumed to have an individual developmental pace that needs to be respected. Also child care guide books do not offer information about motor stimulation, whereas all kinds of cognitive competencies are detailed. Yet this is not considered training, but necessary stimulation. It is obvious that early motor independence supports action autonomy, whereas early cognitive competencies support psychological autonomy (Keller & Kärtner, 2013).

On the other hand, infants are swaddled or kept otherwise immobile for substantial parts of infancy in some cultural environments (e.g., Hopi Indians: Dennis & Dennis, 1940; Aché Indians: Hill & Hurtado, 1996). This is the case particularly in contexts where multiple dangers are lurking on the ground, like fire or venomous animals. Children develop independent sitting, crawling, and walking comparatively late. There is obviously an almost 2-year-long window of opportunities for the acquisition of gross motor milestones.

Another example of cultural precocity during the first years of life is the attainment of self-recognition. The emphasis on children's psychological separateness and independence in Western middle-class families allows toddlers to develop early mirror self-recognition, as the first indicator of a sense of self as an autonomous intentional agent. The *rouge test* is the standard procedure for assessing mirror self-recognition (Amsterdam, 1972). A colored mark is surreptitiously placed on the child's face before he or she is exposed to a mirror. Self-recognition is conceded if the toddler shows clear mark-directed behavior (e.g., by touching the mark).

In a cross-sectional and longitudinal study design, Kärtner, Keller, Chaudhary, and Yovsi (2012) demonstrated marked differences in the timing of mirror self-recognition. At the age of 18 months, 46% of the urban German and Indian toddlers recognized themselves in a mirror, but only 11% of rural Indian and about 9% of the rural Nso sample did so. Therefore, culture-specific emphases on psychological autonomy influence the onset and further development of mirror self-recognition. Across cultural environments, the percentage of toddlers who recognize themselves in the mirror generally increases with age. However, there is a steeper increase for

this attainment in psychological autonomy-supporting cultural milieus; toddlers in these cultural contexts develop mirror self-recognition faster.

It can be assumed that a distal interactional strategy, especially face-to-face contact, visual contingent responsiveness, and object stimulation during the early months of life support the early development of self-recognition. In fact, these relationships have been confirmed empirically in cross-cultural studies. Regardless of cultural context, the more face-to-face contact, visual contingent responsiveness, and object stimulation that children experience at age 3 months during mother–infant interaction, the greater the likelihood that toddlers will recognize themselves in a mirror at 19 months of age. Since cultural environments differ with respect to the prevalence of distal socialization strategies, cultural differences in mirror self-recognition emerge (Keller et al., 2004b; Keller, Kärtner, Borke, Yovsi, & Kleis, 2005b). What seems to be critical in this regard is the degree to which caretakers direct infants’ attention to their own internal states as part of the distal socialization strategy, thus socializing for psychological autonomy (Kärtner, 2015).

The development of self-regulation is also subject to cultural precocity. According to the different cultural socialization emphases, it has been demonstrated that sub-Saharan toddlers comply more readily with requests than do toddlers in European American middle-class families. Running chores independently and precisely as requested is part of the understanding of a good and intelligent child (Teiser et al., 2018; Ogunnaike & Houser, 2002). Compliance with others’ wishes—and therefore self-regulation—is a prerequisite for exercising responsibilities in a large household and therefore a socialization pathway toward hierarchical relatedness (Keller et al., 2004b; Munroe & Munroe, 1975; Whiting & Whiting, 1975).

Dynamics of Developmental Processes

Since developmental tasks are considered panhuman themes, it is obviously the case that all children eventually walk and recognize themselves in a mirror. However, this does not imply that these achievements are acquired the same way across cultures. An example of different developmental dynamics has been demonstrated with the development of empathy during

the second year of life (Kärtner, Keller, & Chaudhary, 2010a). Empathy, a panhuman emotion, is considered to be based on the differentiation between self and others. Concern for another person's feeling and the urge to console an obviously distressed social partner are seen as independent from one's own emotional situation. In fact, in Western middle-class samples, an empirical link between self-other differentiation as assessed in mirror self-recognition and empathic concern has been demonstrated (Bischof-Köhler, 1989; Zahn-Waxler, Radke-Yarrow, Wagner, & Chapman, 1992). In a cross-cultural study, however, Kärtner and colleagues showed that comforting others was preceded by self-other differentiation (again, assessed with mirror self-recognition) only in a psychologically autonomous cultural milieu, in this case among Berlin middle-class families. In an urban middle-class sample from Delhi, where families endorse socialization goals representing both psychological autonomy and hierarchical relatedness, the relationship between self-other differentiation and empathic concern could not be established. Kärtner and colleagues (2010a) therefore concluded that it seems unlikely that emotion-related helping behavior depends on self-other differentiation as a universal social-cognitive precondition. An alternative interpretation might be that situational prosocial behavior is based on shared intentional relations (Barresi & Moore, 1996). Children understand intentional actions of others by experiencing and sharing the same mental state, without ascribing their own independent experience to the other person. Thus, *situational* helping behavior is an alternative to empathically motivated helping behavior. These different developmental dynamics constitute different developmental pathways to the toddler's development of prosocial behavior.

Another example of different developmental dynamics underlying similar developmental achievements may be found in autobiographical remembering by 3-year-olds during joint reminiscing with their mothers. In samples from Berlin and Delhi, Schröder and colleagues (2011, 2012) demonstrated that children's memory contributions during joint reminiscing were differentially predicted by maternal and child responsiveness when the children were 19 months old). Whereas the *mothers'* responsiveness to play initiatives from their 19-month-olds was the best predictor of children's memory elaborations during joint reminiscing in the urban middle-class families from Berlin, it was the *19-month-olds'*

responsiveness to maternal requests that was the best predictor in the Delhi sample. These results support the interpretation that 3-year-olds' memory contributions have different functions during joint reminiscing. Whereas, in the Berlin sample, the initiative for joint reminiscing is given to the child and the mother confines herself to assisting the child in recollecting the specific event under question, mothers in Delhi take the lead and expect their children to remember the specific event as well as possible.

These studies illustrate that even if, on a surface level, toddlers' development looks similar in two ecosocial contexts—the Berlin and Delhi children were equally elaborative—the underlying dynamics might differ, because the developmental processes are embedded in a wider context of culture-specific meanings and interaction formats. And these formats again correspond to the cultural models specifying psychological autonomy and hierarchical relatedness, and their possible combinations.

Developmental Gestalts

In the preceding paragraph, we argued that similar developmental achievements can be expected in various domains across cultural environments, although the underlying dynamics may be different. In the following paragraph, we argue that the phenotypic appearance may also differ.

An example is the so-called *2-month shift*, which indicates a developmental transition in the way infants interact with their social environment. At about 2 months of age, infants have been described as becoming more attentive to social partners, looking longer at others' faces, and starting to smile socially. This qualitative behavioral change has been ascribed to maturational processes in the developing brain (Wolff, 1987). In more recent times, the importance of specific social experiences, especially face-to-face contact, has been acknowledged (Holodynski & Friedlmeier, 2006; Messinger & Fogel, 2007), without taking into account that cultural environments differ substantially in their socialization strategies and the provision of face-to-face contact specifically. As described before, infants of Nso farmers, for example, do not experience face-to-face contact to the same degree as do babies from Western middle-class families. Nso infants

showed a similar sharp increase in awake alertness between weeks 6 and 8, as do Western middle-class infants, but their interest in gazing at their mothers' faces was significantly less pronounced and did not change with age. This pattern corresponded to mothers' interactional style that did not increase its emphasis on face-to-face exchange (Kärtner, Keller, & Yovsi, 2010b). Similarly, social smiling increases for babies, as well as for mothers, in German middle-class dyads, whereas it remains unaffected by maturational changes in the Nso dyads. These findings support the notion that culture-specific scripts as embodied in behavioral strategies interact with maturational processes, leading to diverse developmental results and Gestalts.

Another example relates to "stranger anxiety," which is children's wariness, discomfort, and fear when confronted with an unfamiliar adult. It is assumed to occur around approximately 8 months of life (8-month anxiety; e.g., Spitz, 1965; Sroufe, 1977), when children are considered to be able to discriminate between familiar and unfamiliar people. It is regarded as a part of a universal behavioral system that evolved to protect the infant from hazards such as dangerous predators in the environment of evolutionary adaptedness (EEA), in which our genes are assumed to have evolved (Daly & Wilson, 1988; Hrdy, 1999; Ainsworth et al., 1978). The predisposition for stranger anxiety belongs certainly to the evolutionary heritage and may be regarded as part of the panhuman system of basic emotions such as interest, joy, sadness, anger, disgust, and fear (Izard, 2009). However, emotional experience and expression of emotion are also part of socialization strategies that differ substantially across cultural contexts (Matsumoto & Hwang, 2011). Also, the occurrence of stranger anxiety depends on the ecosocial context, in particular, social organization. In small-scale rural environments such as Beng villages in Ivory Coast (Gottlieb, 2014), Gusii villages in Kenya (LeVine & LeVine, 1988) or Nso villages in the northwest of Cameroon (Otto, 2008), stranger anxiety is not observed and may not be a necessary adaptation for the protection of small children. In line with the contextual demands and the cultural model of hierarchical relatedness, Nso families do not value the expression of emotions in children and do not encourage or mirror emotional expressions such as smiling, as the 2-month shift study has demonstrated. Caregiving strategies generally consist of calming instead of arousing, which

corresponds to the cultural belief that a calm child is a good and healthy child. Quiet and calm children are easy children, who do not need extra attention and may be cared for by multiple caregivers.

Hiltrud Otto (2008) conducted a standardized observation study in the Nso villages around Kumbo with a female adult stranger approaching 1-year-old children at home, when they were close to their mothers. After greeting the mother, the stranger approached the child, picked him or her up, and turned away from the mother. Most of the children did not express any emotion during this situation and displayed a neutral face; moreover, these children showed a decrease in the stress hormone cortisol from the moment the stranger appeared in their visual field (distal approach) to the moment the stranger picked them up after a couple of seconds (proximal approach). This behavior was what the mothers expected from a good child, as they explained in interviews. However, a small group of children displayed stranger anxiety combined with a high level of cortisol and an increase in cortisol from the distal to the proximal approach. These children lived with their single mothers in the maternal compound, whereas children who reacted with emotional neutrality lived with their married mothers in the paternal compound, which is the socially normative family arrangement.

Ibtisam Marey-Sarwan found similar contextual variations within cultural environments with Bedouin families living in unrecognized villages in the Maqab in Israel (Marey-Sarwan et al., 2016). In line with the close-knit social environment in extended families within the large compounds, those 1-year-old children did not display stranger anxiety in the same standardized stranger approach situation. However, there was a group of children that displayed stranger anxiety; they lived in smaller families, who were very much aware of the dangerous living situation due to sociopolitical circumstances.

These findings underline the importance of studying contextual variation, especially when behavioral qualities are envisaged. Generally, these and other findings have substantial consequences for the conception and the development of attachment. There is no doubt that there is a basic human need for the development of attachment relationships, but the Gestalts that emerge in particular contexts may differ substantially (Otto & Keller, 2014; Quinn & Mageo, 2013). Attachment theory is a case in point when a cultural reformulation is especially important. Attachment theory is

widely applied in the clinical and educational fields, and serves as the scientific basis for policy decisions of major institutions such as UNESCO or the World Bank. Attachment theory, however, is clearly based on the European American middle-class child care ideology of the Cold War period of the 1950s and 1960s (Vicedo, 2013, 2017; Morelli & Rothbaum, 2007; for discussion, see Morelli et al., 2018a, 2018b). In the following section, we summarize the major tenets of attachment theory.

ATTACHMENT THEORY: A CASE IN POINT

The British psychiatrist John Bowlby was the first to bring together diverse theoretical perspectives as summarized in his trilogy *Attachment and Loss*, publishing the first volume, *Attachment*, in 1969. He presented a new understanding of relationship formation that started to abandon Freudian (1940/1964) perspectives on development, which assume attachment to the mother is a co-occurring phenomenon of an infant's pleasure in nursing during the so-called "oral stage" (see also Johow & Voland, 2014). Bowlby synthesized knowledge from his clinical practice with systems theory and some aspects of ethological/primatological and evolutionary approaches. Experiments conducted by Harry Harlow with chimpanzees in his laboratory in Madison, Wisconsin, were especially influential. Harlow convincingly demonstrated that deprived chimpanzee infants preferred "contact comfort" (i.e., a surrogate mother made of wire and covered with cloth, more than one offering food). Bowlby came to emphasize that the mutual motivations of the mother and the child to be near each other represented a behavioral system. He interpreted this system as a biologically functional behavioral structure with the purpose of survival and reproduction. However, he neglected the already available knowledge about cultural variation in children's development, an aspect that was already criticized by Margret Mead (see Vicedo, 2017).

Mary Ainsworth, a Canadian psychologist, who joined Bowlby in London in the early 1950s, was the first to empirically study attachment and its development, focusing her attention on interindividual differences. Based on natural and longitudinal observations in Uganda, she described three groups of infants' attachment behaviors: securely attached, insecurely

attached, and nonattached infants. She concluded that maternal sensitivity is the crucial determinant of attachment quality, which she later defined as the “ability to perceive and interpret accurately the signals and communications in the infant’s behavior and, given this understanding, to respond to them appropriately and promptly” (Ainsworth, Bell, & Stayton, 1974, p. 127). Although Ainsworth’s empirical work started out in Uganda, her conception of sensitivity is clearly part of the cultural model of psychological autonomy, as previously outlined (see Keller et al., 2018). Ainsworth had started a longitudinal study in Baltimore in order to systematically examine relations between maternal behavior and later infant attachment. She visited mothers and their babies once every month at home from birth on, for a period of 1 year (Ainsworth et al., 1978). However, she could not replicate the observations made in Uganda that infants were distressed by the separation from their caregiver. The “Baltimore babies were used to having their mothers come and go, come and go, and they were much less likely to cry when their mother left the room” (Karen, 1994, p. 146). Since they were used to brief absence of their mothers, their attachment system did not become activated. Ainsworth therefore developed the most prominent laboratory assessment in developmental psychology, the Standardized Strange Situation Procedure (Ainsworth et al., 1978; Karen, 1994). In this procedure, a child is observed in the laboratory for 20 minutes while the mother and a stranger enter and leave the room alternately, under conditions of increasing stress. Observing the child’s responses with regard to the separation and reunion with the mother and the amount of the child’s exploration revealed the expected differences; children were categorized into three groups: securely attached, insecurely avoidant, and insecurely ambivalent attached. Later, Mary Main added a fourth category, disorganized attachment (Main & Solomon, 1986, 1990), which is characterized by bizarre infant behaviors such as freezing, crouching on the floor, and other depressed behaviors in the presence of the caregiver during the Strange Situation. Disorganized attachment is considered to be an early predictor for the development of psychopathology from the preschool period onward (Henninghausen & Lyons-Ruth, 2005; Thompson et al., 2005).

Variability in the U.S. infants’ behaviors in the Strange Situation could be linked to the former home observations and yielded relationships with maternal sensitivity. Ainsworth’s classification of 106 U.S. children set the

benchmark for later research, constituting the “American Standard Distribution”: 66% secure, 12% avoidant, 22% resistant (ambivalent) (Ainsworth et al., 1978). However, the relationship between maternal sensitivity and security of attachment could not be sufficiently replicated in follow-up studies. Meanwhile, mind-mindedness (Meins et al., 2003) or maternal reflective functioning (Fonagy et al., 2002), that is, verbalizing the mental states of the infant, emerged as precursors of attachment security.

According to attachment theory, at about 1 year of age, children should have developed a primary attachment relationship, in the best case a secure one, to the significant caregiver, mainly the mother. Though originally conceived of as monotropic (i.e., directed to one person), relationship conception was later modified to include also (a few) other attachment relationships (e.g., the father). Nevertheless, there is one primary relationship to which others may be subordinated.

Attachment is conceived of as an emotional bond, which is expressed in attachment behaviors such as crying, clinging, and following, with the aim of establishing and maintaining proximity to the caregiver, particularly in stressful situations (e.g., Bretherton, 1992). The attachment quality eventually becomes represented in an internal working model as the model for all future relationships. Moreover, the attachment relationship is considered to be predictive of socioemotional and cognitive development in general (Antonucci & Levitt, 1984).

Due to the assumed evolutionary origin of attachment, attachment theory proponents claim universality of its emergence, its appearance, and its consequences (e.g., van IJzendoorn & Sagi-Schwartz, 2008). This assumption however has been repeatedly challenged, lately with the publication of several volumes, presenting evolutionary, cultural/cross-cultural and historical evidence that delineate the Bowlby/Ainsworth attachment theory clearly as a Western middle-class phenomenon of the post war period (Otto & Keller, 2014; LeVine & LeVine, 2016; Quinn & Mageo, 2013; Vicedo, 2013, see also Harkness, 2015; Keller & Bard, 2017). The major discrepancies occur in the following domains:

1. Definition of attachment: Attachment theory defines attachment as an emotional bond. In many other cultural environments (e.g., traditional farming communities), relationships are based on social values such as

duty, obligation, respect, and responsibility, with emotions regarded as disruptive.

2. Attachment is organized as the primary relationship between a baby and one adult caregiver, mainly the mother, and may be supplemented by few others in the attachment theory framework, but in many cultural environments it may be organized in a system with several caregivers, who may be adults or children.
3. The development of attachment relationships is situated in the caregiving context. However, caregiving experiences differ along the dimensions of distal and proximal parenting and attention distribution across cultures. As described earlier, exclusive dyadic face-to-face contact with the expression of (positive) emotions and embedded in voluminous verbal quasi-dialogues is characteristic of Western middle-class parenting, whereas body contact and motor stimulation and distributed attention are channels of communication in non-Western farming communities. One conception of sensitivity cannot capture these differences.
4. Attachment theory is child centered, focusing on the individual child, especially his or her mental states, and assigning the lead to the child. In contrast, many other child care philosophies assign the expert (parent, older sibling, peer) the lead and prioritize the social system.

Evaluating attachment relationships implies always a moral judgment (Morelli et al., 2018b). However, dysfunction and pathology also need to be defined within contextual frameworks. As we have discussed in previous sections, what is considered a necessary condition of development for one developmental pathway (e.g., face-to-face contact for Western middle-class socialization) is considered unimportant or even detrimental to developmental progress (e.g., for the proximal strategy). Nso women, for example, blow into infants' faces in order to discourage face-to-face contact (Keller & Otto, 2011). Gernhardt, Keller, and Rübeling (2016) analyzed the family drawings of 6-year-olds from German middle-class and Cameroonian Nso farmer communities with respect to coding schemes that were developed by attachment researchers to classify children as securely or insecurely attached. It turned out that the majority of German middle-class children was classified as securely attached, whereas the majority of Nso farmer children was classified as insecurely attached, since the same drawing

characteristics hold different cultural meaning. What is classified as signs of insecure attachment (e.g., leaving the mother out of the drawing, small body size, no facial features) is the cultural standard of family drawings in the Nso farmers' world. These differences are based on the different conceptions of the self and social realities. There is no evidence regarding what these differences mean for children's developmental trajectories. Although the "competence hypothesis" (i.e., the assumption of a relationship between quality of attachment and later competence) is one of the core assumptions of attachment theory (Mesman, van IJzendoorn, & Sagi-Schwartz, 2016), there is a general lack of studies (in both the West and non-West) addressing this association directly (Groh et al., 2014). There are some studies showing relationships between nutritional status/health and attachment security in non-Western rural children, where it remains unclear what is cause and what is effect (for a discussion, see Mesman et al., 2016). However, in order to establish links between attachment security and later adaptive functioning, it is first necessary to assess the meaning of attachment and attachment relationships in diverse cultural environments. A precondition is the careful assessment of sociodemographic contexts, an encompassing ethnography of the living conditions and social networks, behavioral observations in the natural environment during daily practices, and the assessment of the meaning that local people attribute to the behavior and practices (for more extensive discussion, see Gaskins et al., 2017). Applying an observational protocol (e.g., the Strange Situation), a precoded list of attributes or predefined rating systems (like that for children's family drawings) is not suitable for assessing local meaning systems and cultural priorities (LeVine & LeVine, 2016). Interestingly enough, Ainsworth (Ainsworth & Marvin, 1995, p. 12) had repeatedly expressed her disappointment "that so many attachment researchers have gone on to do research with the Strange Situation rather than looking at what happens in the home or in other natural settings. . . . It marks a turning away from 'field work' and I don't think it's wise."

Overall, the discussion of the different developmental mechanisms clearly demonstrates that basic human themes and developmental tasks need to be solved in line with contextual-cultural demands in order to be adaptive and provide the necessary endowment for mastering life successfully. It has also shown that the two cultural prototypes,

psychological autonomy and hierarchical relatedness, provide useful frameworks for understanding cultural variability. This should not be misunderstood as meaning that there is a global great divide with two prototypes and some variation. There are universals (e.g., developmental tasks) that are common to all cultures, commonalities for some cultural groups (shared norms, values, and behavioral conventions) and subjective idiosyncrasies. However, some anthropologists argue that every culture is unique, and any kind of classification or clustering is inappropriate (e.g., Gergen, Gulerce, Lock, & Misra, 1996). In that sense, the concept of culture is assigned to individual (ethnic) groups. The concept of culture in this chapter is assigned to *sociodemographic* milieus. Therefore, commonalities can be identified across ethnic, geographical, or societal boundaries. Yet the empirical database of child development on a global scale is still largely limited, so that more variability and other dimensions may emerge with more research.

CONCLUSION

Culturally informed accounts of child development necessitate culturally informed methodologies (Cohen, [Chapter 6](#), this volume). Taking assessment procedures that are developed in one cultural context to another implies multiple biases that start with conventions of social behaviors (e.g., general modes of conduct between children and adults) and end with the meaning of the assessed behavior (construct validity). It is as much a problem of the social entree and communications rules in the community as it is one of equivalence of meaning, method, measures, and procedure (Abukabar et al., 2007; Keller, 2011; Lamm & Keller, 2011; Teiser et al., 2018). Nevertheless, the bulk of cross-cultural studies uses standardized Western procedures and tests (e.g., the Strange Situation Procedure to assess attachment security; see Mesman et al., 2016). The culture(s) of study participants is equated with nationality or membership in an ethnic group. Samples in empirical studies are often poorly described, which further compromises the meaning of research results. In contrast, the differential conception of development as presented here rests on the specification of

the ethnographic and sociodemographic milieus as a necessary part of the study.

Description, explanation, and prediction as the three tasks of developmental psychology in general can only be accomplished with a multimethod repertoire (Hay, 2016). Quantitative and qualitative methods need to be combined across disciplinary boundaries. Research methods that have been developed in psychology, such as systematic observations, questionnaires, and interview techniques, gain meaning and substance with ethnographic analysis and spot observations from anthropology, with lifespan analysis from evolutionary approaches, and with neurophysiological data from neurocognitive sciences. Combining different methodologies representing different research paradigms represents a major shift in orientation; for a long time, methods have been seen as integral parts of research paradigms, so that combining methods from different paradigms seemed to be incompatible (Reese & Overton, 1970)

Cooperation of researchers representing different cultural backgrounds should become the reality of cross-cultural research programs (Chaudhary, 2004; Nsamenang, 1992; Saraswathi & Pai, 1997). The view from inside is necessary for meaning making, but the view from outside may help to highlight questions that may be unnoticed from inside because of the invisible, obvious nature of culture.

The systematic inclusion of culture into developmental psychology is also crucial for application. The major programs of prevention and intervention applied in rural non-Western contexts are mainly based on Western theories. Family support programs, transition to parenthood programs, and counseling practices rest on the assumptions of attachment theory, which embodies a prototypical psychological-autonomous orientation, as outlined earlier. Training mothers to foster attachment during breast-feeding with exclusive face-to-face contact does not fit the reality of farmer women (Morelli et al., 2018b). Also, nonacceptance of these programs in Western countries by families from lower socioeconomic backgrounds and those who have migrated from rural areas may be rooted to a large extent in clashes of cultural milieus that have different philosophies of child rearing. Serpell and Nsamenang (2014) have compiled a programmatic document for UNICEF that pleads for the inclusion of local standards and evaluations for applied programs. Applying the child-rearing

philosophy of one cultural context to other cultures, without proving its fit with local meaning systems and the wider implications for the social dynamics of the community, poses substantial ethical problems (Morelli et al., 2018b).

Another important area of application is early childhood education, as outlined in day care and kindergarten curricula. These institutions also are oriented toward psychological autonomy, which often dramatically contradicts the educational theories and practices of migrant families from rural villages and embodies the cultural model of hierarchical relatedness (Gonzalez-Mena & Widmeyer Eyer, 2008; Greenfield, 2004; Borke & Keller, 2014). The withdrawal of these families from early education reduces children's chances for successful participation in the educational system through preparation for schooling.

The complexity of humans' nervous systems and the multiple facets of the context and environment do not allow formulation of a single adaptive relation between context and behavior, and a single healthy and normative developmental pathway (cf. Belsky, Steinberg, & Draper, 1991; Chisholm, 1992; Cole & Packer, 2016; Greenfield & Suzuki, 1998; Keller, 2000, 2007; Keller & Greenfield, 2000; Keller & Kärtner, 2013; Rothbaum et al., 2000a, 2000b). Studying developmental pathways as the cultural solution to universal developmental tasks is thus both an exciting basic research agenda and a most important field of application.

NOTES

1. Formal education is not considered here as being superior to nonformal education; it is a different mode of education with different goals and different topics. Moreover, formal education may look very different in different locations (Döge & Keller, 2012; Gernhardt, Lamm, Döge, & Keller, 2014). Also, the formal education in religious schools is not addressed here.

2. This does not mean that no other cultural models exist.

CHAPTER 16

Cultural Psychology of Moral Development

**Joan G. Miller, Matthew Wice, and Namrata
Goyal**

This chapter provides an overview and critical analysis of research on culture and morality. Throughout the discussion, consideration is given to the extent to which the major theoretical perspectives on morality in psychology embody moral pluralism, in the sense of taking into account multiple types of moral concerns, and cultural contextualization, in the sense of taking into account cultural variability in moral outlooks. The first section reviews classic and contemporary models of moral development. It is shown that the field has moved over time in pluralistic directions by going beyond models that treat justice as the sole moral content to models that incorporate concerns with caring and with divinity. The second section identifies challenges for future theory and research. These include the need to bring greater cultural sensitivity to taxonomic models of morality, and to develop a greater appreciation for the value and challenges associated with the forms of cultural relativism associated with cultural psychology. The third section outlines future research directions that include understanding the culturally variable developmental pathways through which moral outlooks emerge, and bringing a cultural perspective to understanding power dynamics and intergroup relations. Finally, we highlight the importance of appraising alternative cultural moral commitments in ways that are appreciative of their coherence and sensitive to their real-world applications.

Morality is central to culture. As Shweder (1999) has noted, culture involves “community-specific ideas about what is true, good, beautiful and efficient that are . . . constitutive of different ways of life, and play a part in the self-

understanding of members of the community” (p. 212). Although cultures involve shared moral commitments (e.g., D’Andrade, 1984; Strauss & Quinn, 1997), the issue of whether morality is culturally variable remains controversial.

Our goal in this chapter is to provide a critical analysis of research on culture and morality, and to identify contributions of work in this domain. We present in the first section an overview of the major theoretical approaches to morality, with consideration given to cultural work that bears on the claims of these approaches. This is followed by a discussion of challenges in contemporary work in cultural psychology on morality. In turn, in the final section we identify new directions for future theory and research. Throughout this discussion, critical consideration is given to the extent to which the theoretical and empirical perspectives on morality under consideration embody moral pluralism, in the sense of recognizing the existence of multiple rather than only unitary moral outlooks, and on whether they incorporate cultural contextualization, in the sense of taking into account culturally variable outlooks.

MAJOR THEORETICAL APPROACHES AND CULTURAL CHALLENGES

We consider both classic and contemporary theoretical models of moral development, including Kohlbergian stage theory, distinct domain theory, the morality of caring, and moral ethics perspectives. In each case, discussion centers on the theoretical assumptions of the models and on work in cultural psychology that bears on their claims.

Kohlbergian Stage Theory

Kohlbergian Approach

Kohlberg’s cognitive-developmental stage model of moral development was one of the most influential frameworks in the field, inspiring later work in developmental psychology and playing a major role in establishing moral development as a field of psychological inquiry (Kohlberg, 1969, 1971,

1981). The model grounds morality in philosophical arguments that Kohlberg saw as providing an objective basis for morality and is distinguished by its stage model. Groundbreaking in its time and dominating research on moral development for many decades, the Kohlbergian model presented a universalistic developmental approach.

Part of the Cognitive Revolution in psychology and drawing heavily on Piagetian theory, Kohlberg made a sharp break with the then dominant behaviorist and psychoanalytic models of morality (e.g., Berkowitz, 1964; Freud, 1930). Piaget (1932, 1973) had rejected behaviorist and maturational approaches to cognitive development because, in his view, they treated knowledge as merely a copy of information given in the environment. Piaget furthermore assumed that cultural approaches resemble behaviorist perspectives in embodying a passive view of the child. Kohlberg adopted these same assumptions in also assuming that cultural learning involves passive processes of conformity to culturally specified understandings (Kohlberg, 1971) rather than active interpretive processes that entail going beyond the information given in experience (e.g., Bruner, 1973).

Beyond this view shared with Piaget that cultural approaches assume a passive view of development, Kohlberg, however, raised concerns about the problematic nature of the relativistic morality that he felt inhered in giving weight to culture. In adopting this stance, Kohlberg forwarded a model that rejected both moral pluralism and cultural contextualization. Kohlberg (1971, p. 159) criticized the “relativist point of view” held by anthropologists as assuming “the validity of every set of norms for the people whose lives are guided by them.” Kohlberg also pointed to the logical contradiction of relativistic appeals for tolerance of other people’s beliefs as a stance that treats the principle of toleration itself in nonrelative terms.

To construct a universalistic morality, Kohlberg grounded his theoretical model in Western philosophical premises (Rawls, 1971). In this view, to be moral, an outlook must meet the formal criteria of being universally applicable, prescriptive, and capable of being applied in an impartial and impersonal manner. Issues that relate to social position or to affective considerations are excluded from such a morality. The six-stage developmental sequence of moral development forwarded by Kohlberg (1969) treated role-related and affective considerations as reflecting lower forms of reasoning that are associated with premoral stages of development.

The most developmentally primitive stance formed the preconventional level, focused on affective and other self-interested concerns, including a stance of avoiding punishment (Stage 1) and of instrumental exchange (Stage 2). In turn, the developmentally more advanced conventional level encompassed relationship and role-related considerations, including a focus on role expectations (Stage 3) and on the rule of law and other societal-level concerns (Stage 4). Finally, the developmentally highest level, the only level at which reasoning is considered fully moral in nature, included a stage focused on individual rights that have been agreed upon by the whole society (Stage 5) and a stage focused on self-chosen principles of justice, human rights, and respect for the dignity of individual persons (Stage 6).

The methodology utilized in Kohlbergian research involved presenting individuals with hypothetical moral dilemmas that portray conflicts involving justice considerations and assessing individuals' open-ended reasoning in resolving these dilemmas. For example, in the Heinz dilemma, one of the most well-known dilemmas used in work in this tradition, respondents are presented with a situation in which a husband is faced with whether to steal the only medicine that will save his dying wife from a druggist who is charging exorbitant prices. Although this type of methodology succeeded in evoking highly reflective moral reasoning, its linguistic complexity made it difficult to answer for children and other populations with limited education, as seen in the findings of marked social class and developmental differences on Kohlbergian measures (Snarey, 1985).

The Kohlbergian model was subject to extensive cross-cultural testing that Kohlberg interpreted as supporting the universality of his model, despite the consistent findings of cross-cultural variation in the highest stages of moral reasoning achieved (Kohlberg, 1969, 1971; Snarey, 1985). Thus, for example, whereas most U.S. respondents reached the postconventional level of moral development, the dominant form of reasoning attained by non-Western and rural populations was only at the conventional level. This result—that higher levels of moral development are linked to Westernization, education, and urbanization—was interpreted by Kohlberg as evidence for particular environments being more stimulating than others and therefore more effective in stimulating moral development.

Cultural Evidence

Contemporary research by cultural critics of the Kohlbergian stage model pointed to the need to expand conceptions of the postconventional level to take into account communitarian cultural outlooks (Snarey, 1985; Snarey & Keljo, 1991). This represented a call for both moral pluralism, in pointing to the need to recognize communitarian concerns and not merely justice issues as moral outlooks, and for cultural contextualization, in highlighting qualitative cultural variation in types of communitarian concerns. For example, research undertaken among Israeli kibbutz members identified a concern with cooperative equality and the equal right to happiness of all persons that is not represented as postconventional within the Kohlbergian model. Such a theme is illustrated in the following responses given by a kibbutz member to the Heinz dilemma: “I think the community should be responsible for controlling this kind of situation. The medicine should be made available to all in need. . . . We need this cooperation among ourselves in order to achieve this better world. . . . The happiness . . . principle underlies this cooperation—the greatest happiness for the greatest number of people in the society” (Snarey & Keljo, 1991, pp. 408–409).

In another example, Snarey and Keljo (1991) noted respects in which values of filial piety were reflected in the responses of Chinese respondents to a Kohlbergian vignette that presented respondents with the dilemma of how a son should respond after his father breaks his promise to use money earned by the son to pay for the son’s camp and instead wants to spend the money on himself. One Chinese respondent justified why he felt the son should give his father the money: “In terms of parent–child relations, he has the role as father, and the son should fulfill whatever his father wants. This is because the father has reared Joe for such a long time and given him affection and protection. So Joe should give his father the money to show how much he appreciates his father’s caring” (in Snarey & Keljo, 1991, p. 413).

This type of felt responsibility, Snarey and Keljo argue, involves postconventional moral force, even though it is scored as merely conventional within the Kohlbergian scoring system.

Cultural research challenging the neglect of communitarian concerns in the Kohlbergian approach has also uncovered approaches to resolving

Kohlbergian dilemmas that take into account the perspectives of everyone involved and that value the quality of human life and not just the fact of human life. Thus, in responding to the Heinz dilemma, Japanese respondents have resisted fitting into the dichotomous terms of the Heinz dilemma and instead have argued for solutions that meet both of the competing goals (Iwasa, 2001). As a Japanese respondent explained, “Even if Heinz considers that he has tried all available means, other people might be able to suggest other possible measures, and so, he should ask others’ opinions, and try, for example, by posters, writing to the media or whatever. . . . Stealing is not right by any means” (p. 67). From this perspective, the focus centers on not only protecting the wife’s right to life but on ensuring that the wife lives with human dignity, something which, it is assumed, would be jeopardized if her husband stole on her behalf: “matters of justice is [not] . . . living by doing wrong things. If I were his wife, I couldn’t endure that he has to steal for me” (p. 67). Notably, whereas such responses displayed by the Japanese respondents reflect fully moral interpersonal concerns, they are unlike any of the forms of postconventional reasoning recognized within the Kohlbergian model.

In addition to these types of cultural critiques pointing to respects in which the Kohlbergian framework failed to recognize that culturally variable communitarian concerns constitute moral outlooks, theorists also criticized the Kohlbergian methodology for its failure to adopt a morally pluralistic stance that takes into account culturally based moral concerns with divinity. In an essay that highlighted the need to culturally “expand” the meanings informing verbal responses given to Kohlbergian vignettes, Shweder and Much (1987) showed that a response that appears conventional may reflect underlying postconventional concerns with divinity. For example, one of the orthodox Hindu Indian respondents interviewed by Shweder and Much argued that Heinz should not steal the drug to save his wife’s life: “If he steals he would be sent to jail. Then what’s the use of saving her life to keep the family together” (p. 219). In examining the meanings underlying this response, however, Shweder and Much showed that the informant’s view was premised on his sense that it is right that the woman should die to go on with what the informant assumed would be her journey of the spirit through its various rebirths. Also, they noted that the informant considered stealing in this case as a violation of *dharma*, since stealing for someone who is part

of one's family is regarded as self-involved, and *dharma* only allows stealing in cases when it is not self-interested.

Although Kohlberg made some acknowledgment near the end of his career that the emerging cultural evidence may have identified postconventional concerns not taken into account in his theoretical model (Kohlberg, Levine, & Hewer, 1983), he and other contemporary cognitive-developmental theorists never abandoned their rejection of moral pluralism and of cultural contextualization. In the Kohlbergian standard issue coding manual (Colby & Kohlberg, 1987), which came to be treated as the official guide for scoring of responses to Kohlbergian vignettes, the content considered postconventional centered exclusively on issues of justice, with no consideration given to morality as involving other types of content and taking culturally variable forms.

Over time, the Kohlbergian model gradually became less prominent in developmental psychology in response to theoretical and methodological challenges to stage models of development that increasingly were directed at cognitive-developmental theory (e.g., Gelman, 1978). The Kohlbergian model was vulnerable to similar methodological critiques that had been raised in regard to Piagetian theory, with the concern that the methods employed in Kohlbergian research involved highly reflective verbal reasoning that underestimated young children's knowledge. As we describe in the next section, a new theoretical perspective that emerged, distinct domain theory, provided evidence of moral competence earlier in development. Notably, however, this new model retained the assumptions of universalism and a focus on justice morality associated with Kohlbergian theory.

Distinct Domain Theory

The distinct domain framework (Nucci, 2002; Smetana, 1983, 1995; Turiel, 1983, 1998; Turiel, Smetana, & Killen, 1991) challenged the developmental claims of Kohlbergian stage theory, while retaining its focus on justice and individual rights as universally central to morality. Like Kohlberg, then, distinct domain theorists rejected both moral pluralism and cultural contextualization.

As a perspective that continues to dominate contemporary research on morality within developmental psychology, distinct domain theory assumes that social experience is multifaceted, with different types of social understandings applied to different types of behaviors. Rather than considering one type of social understanding as replacing another over development, it is maintained that at any given point in development, individuals apply moral, conventional, and personal choice forms of understanding to different types of issues.

Research in the distinct domain tradition employs child-centered methodologies in utilizing short responses to assess whether individuals are able to distinguish between matters of morality, social convention, and personal choice. To illustrate, Smetana (1981a) presented to preschool-age children drawings of transgressions, such as one child hitting another or not sitting in the designated place during story time. Questions with short answers assessed issues such as the rule contingency of the behavior (“Would it [the depicted behavior] be okay if there was no rule about it here?”), the relativity of the behavior (“Would [the behavior] be okay at home or in another school?”), and whether the behavior is legitimately regulated (“Is it okay for the teacher to punish the child for [the behavior]?”). In this view, categorizing an issue as non-rule-contingent, nonrelative, and legitimately regulated means that it is considered moral; categorizing it as rule-contingent, relative, and legitimately regulated means that it is considered social conventional; whereas categorizing it as non-rule-contingent, relative, and not legitimately regulated means that it is considered a matter of personal choice. This type of research has shown that both preschool-age children and adults are able to distinguish in these ways between issues involving morality, social convention, and personal choice, with the ability to make these distinctions observed cross-culturally (e.g., Song, Smetana, & Kim, 1987).

From the distinct domain perspective, morality is assumed to be based on individuals observing the intrinsic consequences of actions (Turiel, 1983). It is assumed that actions that lead to harm or that infringe on another’s rights are interpreted as matters of morality—such as arbitrarily assaulting another person or taking another person’s belongings without permission. In contrast, it is assumed that other types of social behaviors, such as dress codes, represent social conventions, in that the behaviors serve

to facilitate social coordination and do not involve matters of justice or harm. Finally, it is assumed that there is a domain of personal choice, which involves behaviors that do not involve either moral issues of justice or harm, or conventional concerns of social coordination (Nucci, 1981; Nucci & Lee, 1993). For example, in research on children's understandings of personal issues, Nucci (1981) portrayed personal issues as involving an individual engaging in actions that, while they are counter to a norm, lead to consequences that are assumed primarily to affect only the actor, such as the issue of a girl playing with a friend her parents have forbidden her to see. From this perspective, it is assumed that the content of issues considered in the domain of personal choice is variable, whereas issues considered to be universally moral focus on justice and individual rights.

From the distinct domain perspective, cultural variation in moral reasoning is considered compatible with the assumption that the content of morality is universal. It is argued that cultural differences in moral outlook represent merely cultural differences in background knowledge or underlying epistemological assumptions (Turiel, Killen, & Helwig, 1987; Wainryb, 1991). For example, in judging that it is immoral to eat beef, Indians are seen as maintaining a morality of harm. From the distinct domain perspective, it is assumed that the outlooks of Indians in this case differ from those of Americans only in their assumption that a cow is a sacred object deserving of protection from harm and not in their moral assumption that harm should be avoided.

Cultural Evidence

Work within cultural psychology supports the claims made by distinct domain theorists that concerns with justice and rights exist universally, and that the ability to distinguish between matters of morality, social convention, and personal choice on the basis of formal criteria (e.g., perceived alterability, perceived generalizability) exists early in development and in all cultural groups. However, cultural work challenges the downplaying of cultural processes in the distinct domain model.

Conceptually, work in cultural psychology calls into questions claims that the distinction between the social domains is something that

individuals make, based solely on inductive observation of the consequences of action, and that moral differences derive solely from contrasting informational assumptions. It is noted that acknowledging that matters of personal choice are culturally dependent implies that matters of morality are as well. For example, a matter of personal choice in one culture, such as a child's choice to be friends with someone disapproved of by their parents (Nucci, 1981), may be considered a matter of morality in another culture, depending on the views held of the parent's expectations. Likewise, to maintain that cultural differences can be reduced to contrasting knowledge assumptions neglects the nonrational aspects of social inference (Shweder, 1984). As Smetana (1981b) demonstrated in early work on abortion, theories of the person that inform social categorization of abortion in moral as compared with personal-choice terms reflect deeply held conceptual commitments about personhood that cannot be fully reconciled either logically or empirically. Also, isolating cultural differences in informational assumptions from other aspects of culture may be criticized from a cultural psychology perspective as a stance that holds key elements of cultural outlooks constant while assessing cultural variation.

Empirically, cultural variation may occur in situations in which justice obligations are in conflict with issues that individuals evaluate differently. Thus, for example, Indians have been found to give greater priority to interpersonal responsibilities relative to justice obligations than do European Americans based on their greater tendencies to view interpersonal responsibilities in moral rather than personal choice terms (Miller & Bersoff, 1992). To give an example from this research, whereas a majority of Indians judged that an agent should steal a stranger's train ticket if it was the only way to be able to participate in a close friend's wedding, a majority of Americans judged that the agent should not engage in such a justice violation. Similar cross-cultural differences have been observed in research showing that Chinese children give greater priority to relationship concerns whereas Icelandic children give greater priority to contractual considerations in situations where these two types of concerns conflict (Keller, Edelstein, Schmid, Fang, & Fang, 1998).

Cultural differences in justice reasoning also arise from different weighting of contextual considerations (e.g., Miller, 1984; Morris & Peng, 1994). Thus, for example, Hindu Indians more frequently than do European

Americans absolve agents of moral accountability for justice breaches performed under extenuating circumstances, such as the agent's emotional duress or immaturity (Bersoff & Miller, 1993; Miller & Luthar, 1989).

Cross-cultural variability also occurs in the distinctions made between different types of justice issues. For example, cultural variation has been observed in the "omission" bias, a bias previously assumed to be universal, in which justice breaches resulting from an agent performing an action (e.g., harming someone) are appraised as more serious than are justice breaches resulting from omissions (e.g., allowing someone to be harmed). In research conducted among rural Mayans (Abarbanell & Hauser, 2010), participants were presented with the trolley car hypothetical dilemma that involves protecting five persons about to be hit by a speeding truck through either an act of commission (i.e., pushing a bystander into the road to stop the vehicle) or an act of omission (i.e., failing to warn a bystander who steps into the road without realizing that the truck is approaching). Although populations with diverse cultural backgrounds have shown a consistent tendency to judge the act of commission as a more serious moral violation than the act of omission, rural Mayans judged the two types of breaches as equally serious. In another example of contrasting justice judgments, 7- to 8-year-old children from Germany as compared with children from a hunter-gatherer cultural background differed in their distributive justice judgments (Schäfer, Haun, & Tomasello, 2015). Whereas German children distributed the rewards based on merit, children from a hunter-gatherer society distributed them in an egalitarian manner.

Finally, as we noted briefly in discussion of the distinct domain viewpoint, cultural differences in background premises also lead to marked variation in everyday moral judgment, with individuals disagreeing in their assessment of what entities are assumed to have rights and to be entitled to protection from harm, or even regarding what, in fact, constitutes harm. For example, in maintaining conceptions of the person that involve an emphasis on hierarchy, orthodox Hindu Indian populations from Orissa, India, considered it morally justifiable to accord unequal privileges to females relative to males in inheritance (Shweder, Mahapatra, & Miller, 1987). Also, in holding contrasting conceptions than do Americans of what constitutes harm, this highly orthodox Hindu Indian population regarded corporal punishment of a wife by her husband as morally acceptable, if not morally

expected. Notably, the Oriyan respondents did not consider the husband's punishment of his wife as an example of arbitrary assault but rather of the family head appropriately sanctioning his wife for violating her family responsibilities.

In summary, while cultural research supports claims that justice and individual rights represent universal moral concerns, such research highlights cultural variation in everyday moral outlooks that challenge the rejection of moral pluralism and inattention to cultural contextualization in the distinct domain tradition. The research indicates that cultural variation is associated with justice concerns being accorded different relevance and contrasting priority relative to other types of moral considerations. Cultural differences in conceptions of the entities entitled to protection from harm and in ideas of what constitutes fair distribution of resources also lead to marked differences in everyday moral judgments.

Morality of Caring Theory

In embracing moral pluralism, the morality of caring perspective challenged the focus on justice and individual rights as the core content of morality that was central to Kohlberg's cognitive-developmental model and argued that morality extends beyond issues of justice to also encompass concerns with caring (Gilligan, 1977, 1979, 1982; Gilligan & Wiggins, 1987). Gilligan formulated the morality of caring based on her concern that Kohlbergian research on the morality of justice was gender-biased. In contrast to the emphasis in justice models on morality as being impersonal and impartial, Gilligan forwarded a model that treated morality as involving affective and relationship considerations.

In Gilligan's morality of caring perspective, morality was seen as based on the contrasting sense of self that she assumed males as compared with females develop. Drawing from psychodynamic and attachment theories, Gilligan held that, over development, males and females develop contrasting conceptions of self and associated moral outlooks. In naturally identifying with their fathers, boys were seen as developing an autonomous sense of self and associated morality of justice that is congruent with and supported by the individualism of the larger culture. In contrast, in naturally identifying

with their mothers, girls were seen as developing a connected sense of self and associated morality of caring that is devalued by the individualism of the larger culture. In contrast to the assumption made in the morality of justice that moral outlooks must be impartial, the morality of caring assumes that individuals feel a moral responsibility to be responsive to the needs of individuals in close relationships. Also, in contrast to the assumption that morality is purely cognitive, the morality of caring assumes that caring is based on affective commitments that are other-oriented and non-self-serving in nature. Thus, from the perspective of the morality of caring, a sense of compassion or co-feeling is assumed to develop in the relationships that exist between friends and family, with this sense of co-feeling viewed as providing a reliable basis for moral commitments.

Whereas there was considerable initial interest in Gilligan's claim that morality is gender-related, later empirical evidence challenged this link (Thoma, 1986; Walker, 1984, 1991). The evidence indicated that gender differences in morality tend to be absent or minimal, with any gender-related variation explicable in terms of differences in education, occupation, modes of discourse, or in the types of issues under consideration, such as abortion.

Cultural Challenges

Although embraced as a cultural challenge to justice models of morality, Gilligan's model was itself framed in universalistic terms. Whereas Gilligan's theory adopted a position of moral pluralism, the theory did not embrace cultural contextualization. Thus, the morality of caring, in the view of Gilligan and her colleagues, was assumed to take the same form in all cultural contexts. However, an examination of the illustrative responses cited by Gilligan as evidence for the morality of caring provides evidence that these responses reflect individualistic cultural assumptions. For example, the individualistic emphasis placed by Gilligan's respondents on separating themselves from role-based expectations may be seen in the reflections of a female college student who portrayed herself "in the process of seeking to 'discover what's me' as beginning to get rid of all these labels and things I just don't see as my own" (Gilligan, 1982, p. 53). This respondent further

described how individuality should be linked with caring. Thus, she portrayed her vision of the ideal family as one “where everybody is encouraged to become an individual and at the same time everybody helps others and receives help from them” (p. 54). The individualistic emphasis inherent in the morality of caring model is also evident in the tendency of Gilligan’s respondents to approach interpersonal responsibility as a discretionary stance rather than a matter of role-related obligation. This type of discretionary stance may be seen, for example, in the following representative response cited by Gilligan of a young woman describing her conception of responsibilities of caring: “If you have a responsibility with somebody else, then you should keep it to a certain extent, but to the extent that it is really going to hurt you or stop you from doing something that you really want, then I think maybe you should put yourself first” (pp. 35–36). Rather than a sense of responsibility that is experienced as obligatory or as grounded in role expectations, the sense of responsibility assumed in the morality of caring is contingent on the preferences of the individual.

A program of cross-cultural research undertaken in India and in the United States by Miller and her colleagues challenged the assumed universality of Gilligan’s model in providing evidence that the approach to caring identified in the United States by Gilligan is culturally bound (Miller, 1994). In a series of studies comparing the outlooks of European American and Hindu Indian participants, Miller, Bersoff, and Harwood (1990) highlighted the need for cultural contextualization in the morality of caring in demonstrating that key assumptions made in Gilligan’s approach to caring do not fit the approach to caring held among Indians. One assumption challenged by this cross-cultural work is that the sense of responsibility to care is necessarily discretionary and dependent on the individual’s personal preferences. The research of Miller and her colleagues showed that whereas European Americans tend to categorize helping family and friends as a matter of personal choice, Hindu Indians tend to categorize such helping as a matter of role-related duty that extends to a broader range of need and role situations, including cases involving self-sacrifice (Miller & Bersoff, 1995). The research also challenged the assumption made in Gilligan’s model that caring that is based on role expectations is necessarily experienced as less satisfying than caring that is less socially expected (Miller, Das, & Chakravarthy, 2011). Notably, whereas U.S. participants considered self-

sacrifice for family and friends to be unsatisfying, Indians considered it as a moral requirement to give priority to the needs of family and friends in the face of great personal hardship or sacrifice and associated satisfaction with fulfilling such responsibilities. These contrasting outlooks may be seen in the markedly different reactions given by U.S. as compared with Indian respondents to the hypothetical situation of a wife who remained married to her husband after the husband was severely injured in an accident and unable to meet the wife's needs. In viewing such behavior as a matter for personal decision making rather than moral obligation, a U.S. participant, in a representative response, focused on the dissatisfaction that she anticipated the wife would experience in giving insufficient attention to her personal desires: "She is acting out of obligation—not other reasons like love. She has a sense of duty but little satisfaction for her own happiness" (Miller & Bersoff, 1995, p. 275). In contrast, in a representative response, a Hindu Indian participant noted the satisfaction that she anticipated the wife would experience in being responsive to her husband's welfare and fulfilling her duty as a wife: "She will have the satisfaction of having fulfilled her duty—She helped her husband during difficulty. If difficulties and happiness are both viewed as equal, only then will the family life be smooth" (p. 275).

This program of cross-cultural research also challenged a key tenet of Gilligan's model by calling into question her claim that the morality of caring is unaffected by self-serving affective considerations. Although research by Gilligan and her colleagues provided evidence that supports the claim that caring is associated with moral responsibility to individuals in close relationships, it never tested a key implication of such a claim—that is, the issue of whether self-interested feelings that arise in close relationships can lessen such moral responsibilities or whether, as claimed by Gilligan, they will not. Miller and Bersoff (1998) showed that European Americans maintained that a person has less responsibility to be responsive to the needs of friends and family if he or she personally shares few common tastes and interests with these individuals than if he or she has high affinity and liking for these individuals. In contrast, Hindu Indians maintained that a person's responsibility to his or her family or friends is unaffected by such self-serving considerations.

Although the available research on culture and the morality of caring is limited, evidence suggests that moral outlooks cannot be captured by a

global individualism–collectivism dichotomy; rather, there is a need for even greater cultural contextualization. This work demonstrates that moralities of community found in other cultures differ from both the morality of caring approach identified among U.S. respondents and that observed in the research among Indians described earlier. For example, research among Japanese populations has uncovered an approach that centers on *omoiyari*, or empathy, within one’s ingroup that is normatively based (Shimizu, 2001). Such a stance is reflected in the following response of an adolescent boy who does not report to the teacher a case of vandalism by another student, in empathizing with the student’s desire to retain a supportive relationship with his mother, the school nurse—a relationship that would be disrupted by such a disclosure: “You see, if I became their enemy by accusing them, they would feel uncomfortable to see my mother. . . . So although they destroy school property, I would feel bad for them if they lost someone with whom they could talk about their problems” (p. 463).

In another example, research conducted among Finnish adolescents has uncovered a morality of caring focused on larger social collectives (Vainio, 2015). Specifically, Finnish adolescents felt a responsibility to curtail their individual freedoms as a means to increase the welfare of individual citizens—a perspective influenced, at least in part, by the Nordic welfare system. In still another example, the perspectives identified by communitarian critiques of the Kohlbergian model (e.g., Snarey, 1985) also articulated culturally distinctive approaches to caring. Although these perspectives were put forward before Gilligan had done her work on the morality of caring, and were therefore not explicitly framed as cultural extensions of Gilligan’s model, they may be seen to reflect distinctive cultural approaches to caring that are not taken into account by Gilligan (Snarey, 1985). For example, work among Chinese populations illustrated an approach to community that privileges what is perceived to be the innate, affectively grounded moral tendency of *jen*, “the deep affection for kin rooted in filial piety and extended through the family circle to all men” (Dien, 1982, p. 334).

In summary, whereas cultural research supports the morally pluralistic stance adopted by Gilligan in her claim that a morality of caring includes features not fully captured by a focus on justice and individual rights, this research supports the need for greater cultural contextualization of Gilligan’s

model, in pointing to qualitative cultural variation in interpersonal moral outlooks. Moralities of community, in this view, are multiple rather than unitary in nature, and involve contrasting outlooks on the nature of the affective commitments underlying communal commitments, the discretionary versus duty-based nature of such commitments, and the relationship to different societal collectives and to affective considerations.

Integrative Frameworks

Major Theoretical Taxonomies

In an influential taxonomy of moral beliefs that embraced both moral pluralism and cultural contextualization, Shweder, Much, Mahapatra, and Park (1997) proposed an ethic of divinity as one of the “Big Three” ethics of morality (the other two being community and autonomy). The ethic of divinity approaches morality as a natural sacred order and emphasizes issues of spirituality, such as concerns with purity and degradation (see also A. Cohen & Neuberg, [Chapter 32](#), this volume). In turn, the ethics of community involves moral beliefs related to one’s membership in society and includes the types of concerns discussed earlier as forms of caring. Finally, the ethics of autonomy involve one’s rights as an individual, autonomous being and include the types of concerns with justice and individual rights discussed earlier as central to both the cognitive developmental and distinct domain models.

In forwarding this integrative framework, Shweder and his colleagues built on their earlier work identifying a morality of divinity among Hindu Indian populations. As part of their critique of Kohlbergian interviewing methods, Shweder and Much (1987), for example, provided evidence that informants from an orthodox Hindu Indian temple community justified their judgment that it is wrong for the husband to steal in the Heinz dilemma by referring to negative spiritual consequences that they believed would ensue. Condemning stealing as a violation of *dharma*, the Hindu Indian informants interpreted the act of stealing as leading to spiritual degradation and automatic suffering in cycles of future rebirths (for analysis of Buddhist understandings of *dharma* and related moral concepts, see

Huebner & Garrod, 1991). These types of culturally based epistemological assumptions uncovered by Shweder and Much (1987), it was later shown, inform orthodox Hindu Indians' moral reasoning about a range of everyday social practices, resulting in moral assessments markedly different from those observed among secular populations. Thus, Shweder and his colleagues (1987) observed, for example, that orthodox Hindu populations tended to consider it a moral violation for a wife to eat with her husband's elder brother or for a widow to eat fish, with their reasoning influenced by spiritually based epistemological premises and arguments such as "The husband is a moving god and should be treated with comparable respect" and "The body is a temple with a spirit dwelling in it. Therefore the sanctity of the temple must be preserved. Therefore impure things must be kept out of and away from the body" (pp. 76–77).

Evidence for moralities of divinity that extend beyond justice and welfare have also been observed in other cultural populations, providing evidence for the need to culturally contextualize work on divinity. Haidt, Koller, and Dias (1993) demonstrated, for example, that lower-class Brazilian children and lower-class African American children tended to treat in moral terms disgusting or disrespectful actions, such as eating one's dog, even while viewing such actions as harmless. Reflecting their assumption that humans relate to each other and to the Divine in terms of a hierarchically structured order, fundamentalist Baptist U.S. informants also have been found to consider divorce as a sacrilege, with negative repercussions for the Afterlife (Jensen, 1997). As one informant reasoned: "Divorce to me means [that] you slap God in the face. In other words, you bring reproach upon God. Because Jesus Christ and the church are a form of marriage. What we are saying by divorce is that the bride goes away from the husband. Think about what that means. That means that we could lose salvation. [Divorce] breaks down the very essence of our religion and that's why I think divorce is shameful" (in Jensen, 1997, p. 342).

Shweder's formulation of the Big Three ethics framework has greatly influenced other morally pluralistic and culturally contextualized approaches to studying moral development. The cultural-developmental perspective developed by Jensen (2008), for instance, utilizes Shweder's Big Three ethics to understand how reasoning within each of these moral ethics changes over development. Within research conducted on the cultural

developmental framework, moral reasoning is commonly assessed by conducting interviews and coding open-ended responses in terms of their reference to the ethics, with references to each ethic further coded into subcategories that allow for a fine-grained analysis of responses. In the coding, for example, the superordinate category of divinity includes the subordinate category of “scriptural authority,” which refers to sacred text as a source of moral truth (Jensen, 2004).

Given its emphasis on explaining the developmental trajectory of diverse types of moral outlooks, cultural–developmental theory has forwarded a template for the anticipated developmental timeline for each of the ethics. Within this template, it is proposed that the ethic of autonomy is available early in childhood and remains stable in its usage into adulthood, the ethic of community is available early and increases in emphasis steadily with age, and the ethic of divinity develops only at relatively older ages (e.g., Jensen, 2008). The assumed reason for the delay in divinity reasoning is that a child may not have the cognitive capacity to grasp abstract notions of divinity prior to adolescence (Jensen, 2015). This proposed developmental template, however, is conceptualized as flexible and is anticipated to differ across cultural contexts. For example, with regard to divinity, if the child is exposed to concrete practices and routines that are intertwined with notions of divinity at a young age, divinity reasoning may emerge early in childhood. Such early divinity reasoning is demonstrated in research conducted among Indian children by Pandya and Bhangaokar (2015), showing use of the ethics of divinity early in development. The centrality of divinity in moral reasoning in early childhood may be seen in the following response by an 8-year-old boy: “If we do good for God, God will also do good for us. But if we have broken his idol by mistake and if we don’t tell everyone, then God will be upset and angry. He will like for us to say the truth and to face the consequences. Even if we did it by mistake, he will be happy that we could let everyone know, he will feel less worried and be so proud of us!” (p. 31). This emphasis on divinity among young children is seen as reflecting the children’s diverse daily experiences with practices, rituals, and discourse shaping their understandings of divinity.

In a theoretical formulation that also had its origin in Shweder’s Big Three ethics approach, Haidt and his colleagues formulated moral foundations theory, which, notably, has embraced moral pluralism in

extending Shweder's moral taxonomy beyond the three ethics to what were originally portrayed as five moral foundations (Haidt & Kesebir, 2010; Graham et al., 2011, 2013). However, as will be seen, moral foundations theory does not embrace cultural contextualization, but rather treats each form of morality in fundamentally universal terms.

Moral foundations theory is the most influential framework for understanding morality within contemporary social psychology and accounts for the recent increased interest in morality as a field of study in social psychology, beyond its historical roots in developmental psychology. The aim of moral foundations theory is not only to expand the moral content studied by psychologists, an aim shared with Shweder, but to utilize evolutionary theory to argue for a set of innate moral primitives with roots in natural selection (Haidt & Joseph, 2007). Graham et al. (2011) originally proposed the following as the five universal moral foundations: care/harm, fairness/cheating, loyalty/betrayal, authority/subversion, and sanctity/degradation. The care/harm foundation is seen as being rooted in an evolutionarily deep propensity toward caring for the young and vulnerable; the fairness/cheating foundation as being based on an evolutionary imperative to avoid being cheated; the loyalty/betrayal foundation and authority/subversion foundations as being related to maintaining group cohesion; and the sanctity/degradation foundation as being centered on an extension of the human "behavioral immune system" that, it is assumed, evolved to avoid potentially harmful toxins and contaminants. Since the theory was first posited, a sixth potential foundation of liberty/oppression has also been proposed (Iyer, Koleva, Graham, Ditto, & Haidt, 2012). Moral foundations theory is complementary to Haidt's social intuitionist model of moral judgment, which views moral judgment as being based on intuition, in which deliberate, effortful moral reasoning is seen as functioning as a post hoc justification for moral stances (Haidt, 2001). In contrast to classic approaches to moral reasoning, morality in this view is understood as rooted in subjective perceptions of moral status rather than formal criteria.

Moral foundations theory has been applied to the domain of politics, with a particular focus on America's "culture wars" (Haidt, 2012). Major empirical findings from this tradition have shown that individuals who identify as politically liberal tend to disproportionately reason based on

principles of harm and fairness, giving less attention to loyalty, authority, and sanctity. In contrast, political conservatives tend to utilize all of the foundations in their moral reasoning (Graham, Haidt, & Nosek, 2009; Haidt & Graham, 2007; Haidt & Joseph, 2007).

Cultural Evidence

In contrast to the universalistic perspective of the developmental frameworks of Kohlberg, Turiel, and Gilligan, discussed earlier in this chapter, the present taxonomic frameworks are intended as pluralistic outlooks that are sensitive to cultural variation in moral outlooks. Thus, whereas each of the moral ethic schemes represent abstract frameworks for classifying moral outlooks, they are also intended to capture cultural diversity in moral reasoning. As may be seen, however, whereas the focus on qualitative coding of open-ended responses in work by Jensen and her colleagues on the Big Three ethics is able to tap moral outlooks in ways that are sensitive to cultural context, the adoption of empirical psychometric scale measures in work by Haidt and his colleagues taps moral outlooks in emic terms that are insensitive to cultural variation. Thus, while cultural context is acknowledged within the Big Three and cultural–developmental perspectives, it is not tapped within the methods employed in moral foundations theory.

Exploration of the Big Three ethics that has been undertaken in research on the cultural–developmental framework assesses variation in moral outlooks by examining the reliance placed on each of the ethics in different cultural communities. Reliance on the ethic of divinity, for instance, has been shown to be higher among Brazilians relative to people living in the United Kingdom and New Zealand (Guerra & Giner-Sorolla, 2015). Robust within-culture differences in reliance on the ethics of divinity have been identified, with religious beliefs and practices a major predictor of this variability. Within both the United States and India, for example, use of the ethic of divinity has been shown to be greater among those who are religiously conservative relative to those who are religiously liberal (Jensen, 1997, 2015). These differences in divinity reasoning also vary with context. Research conducted among evangelical and mainline Protestants within the

United States has shown that although evangelical Protestants reason in terms of divinity more for public issues, mainline Protestants show the opposite pattern, relying on the ethic of divinity more frequently when reasoning about private issues specific to their own lives (Jensen & McKenzie, 2016).

Whereas moral foundations theory dominates contemporary work on morality in social psychology and has contributed to an increased interest in the topic of morality within social psychology, this work gives no attention to cultural variability in each of the moral primitives identified. Research on moral foundations theory relies on an individual-difference Likert scale measure, the Moral Foundations Questionnaire (MFQ), developed by Graham and his colleagues (2011). The MFQ taps both the perceived moral relevance and moral judgments of the moral foundations. Whereas the MFQ has revealed marked group differences related to political persuasion (as liberal vs. conservative) and gender, cultural differences on the MFQ have been minimal. Participants from South Asia and East Asia have been observed to endorse ingroup and purity concerns more strongly, while being only slightly more concerned than individuals from the United State, the United Kingdom, Canada, and Western Europe with harm, fairness, and authority. These cultural data are interpreted by moral foundations theorists as supporting the universality of the identified moral foundations, while also indicating that differences in moral outlook between individuals from Eastern and Western cultures are much less than might have been expected.

CHALLENGES IN CULTURAL WORK ON MORALITY

Limited Cultural Sensitivity of Empirical Taxonomic Models

As we described in the previous section, the range of moral content studied by psychologists has expanded in recent years with the formulation of taxonomic models that embrace moral pluralism and the growing body of psychological research on moral issues involving community and divinity. Shweder formulated a taxonomic approach with his identification of the Big Three ethics, with the cultural–developmental approach (Jensen, 2008) and

moral foundations theory (Graham et al., 2011) each extending Shweder's model in distinctive ways that have made the taxonomies more amenable to empirical assessment. In the case of the cultural–developmental approach, Jensen (2004) developed a coding manual for scoring mention of the different moral ethics, whereas in the case of moral foundations theory, Graham et al. (2011) developed the MFQ as an individual-difference measure of moral outlooks. As work on the taxonomic models has developed in these more empirically based directions, however, certain limitations have arisen in the cultural sensitivity of the approaches adopted.

Shweder's argument for the Big Three ethics assumed that moralities entail culturally variable perspectives and need to be understood in emic or experience-near terms. For example, in arguing for the morality of divinity, Shweder presented in-depth analyses of Hindu Indian cultural outlooks, with specific attention to ways of life in the Old Temple town of Bhubaneswar, in which Shweder and Much (1987) conducted their research. Thus, although Shweder and his colleagues (1987) have made use, in cases, of quantitative cross-cultural comparisons, they tap outlooks in relation to local cultural practices that take into account respondents' qualitative reasoning. Also, Shweder and his colleagues include in their research criterion probe judgments to assess whether individuals treat concerns involving autonomy, community, and/or divinity as matters of morality or as matters of social convention or personal choice.

A limitation of the more recent taxonomic approaches, however, is that no distinction is made between issues of morality, convention, and personal choice, with morality instead identified with global judgments of rightness–wrongness. Thus, for example, although Haidt and his colleagues (1993) included criterion probe measures to distinguish between issues of morality, social convention, and personal choice in their early work on non-harm-based forms of morality, they did not include probes to distinguish between issues of morality, social convention, and personal choice in their work on moral foundations theory. In adopting this stance, the contemporary taxonomic models return to the type of stance that confronted Kohlberg as he challenged the approaches characteristic of social learning theory and of Freudian thought that identified morality with any standard that is socially supported or that the individual associates with a strong affective reaction. Kohlberg criticized such stances as glossing over the distinction between

moral and non-moral concerns, and as providing no grounds for identifying moral abuse. In giving no attention to these types of formal distinctions, work on cultural–developmental and moral foundations theory are vulnerable to these same criticisms. Whereas theorists such as Graham and Haidt assume that morality is based on affective responses, in which any cognitive assessment is only a post hoc rationalization, both their approach and that of Jensen (in the coding approach adopted for assessing the ethics of autonomy, community, and divinity) make the questionable assumption that individuals themselves do not make any psychological distinction between moral issues and different types of nonmoral issues. An important direction for future work on moral taxonomies, then, is to take into account the distinctions that individuals make in distinguishing between issues that they consider to be matters of morality, convention, and personal choice.

The empirical instruments adopted to assess moral ethics also have limited sensitivity to cultural context. This methodological limitation is most striking on the MFQ as it is framed in terms of observer-imposed (etic) considerations that gloss over ways that moral concerns are framed in different cultural contexts. For example, whereas research on caring has highlighted its relationship-dependent bases that distinguish it from justice concerns, the MFQ assesses caring as a component of harm and taps it by means of a single decontextualized scale item (i.e., “compassion for those who are suffering is the most crucial virtue” (Graham et al., 2011, p. 385). It is likely that both U.S. and Indian populations would endorse this scale item, despite marked cross-cultural differences in their views of interpersonal morality. This type of effect, then, could explain why few cross-cultural differences have been observed on the MFQ, whereas marked cultural differences in moral outlook between U.S. and Indian populations are found with methods that have greater ecological and ethnographic validity. To give another example, fairness is likewise portrayed on the MFQ items in global ways (e.g., “justice is the most important requirement for a society”) that are likely to be endorsed universally, while providing no insight into the specific ways that norms of justice are applied in different cultural communities and in everyday contexts. As an individual-difference scale measure, the MFQ is easily administered. However, its adoption has had the effect of glossing over cultural variation in moral outlooks and identifying what might be considered spurious moral universals.

Although, with its inclusion of subtypes of each ethic, the coding manual for the ethics of autonomy, community, and divinity developed by Jensen (2015) is more sensitive to cultural context than is the MFQ, but also suffers from limited cultural specificity. For example, although this coding manual includes subcategories that are intended to capture local cultural meanings, it nonetheless fails to tap meanings specific to particular cultural viewpoints. For example, Guerra and Giner-Sorolla (2015) uncovered the lowest endorsement of divinity in Japan in a comparison that also involved samples from Brazil, Israel, the United Kingdom, and New Zealand. However, as they acknowledge, they may have failed to tap certain divinity concerns that are salient among the Japanese, given the tendency of the coding manual to assess divinity only in terms of religious rules and institutions, and not to tap conceptions of divinity based on perceived natural laws that are salient in Japanese culture. Likewise, in research using the three-ethics coding manual in India, Kapadia and Bhangaokar (2015) note the inattention paid to conceptions of divinity and community that entail culturally specific concepts such as *karma*, *paap*, and *dharma/kartavya*. In other work, Hickman and Fasoli (2015) highlight respects in which the treatment of the three ethics as distinct types fails to capture the monistic way these concerns are conceptualized among Hmong families sampled in Thailand. As Hickman and Fasoli argue in reference to the three ethics, “While we find these distinctions to be analytically useful as Weberian ideal types . . . these ideas so deeply interpenetrate one another that it calls into question the empirical utility of these distinctions in characterizing a cultural moral code on its own terms” (p. 147).

It must be recognized that the move to produce coding systems as well as individual-difference scale measures that can be applied universally has limited cultural sensitivity. It is important in future work to enhance the cultural sensitivity of research on the taxonomic frameworks. Whereas the taxonomic formulations of different ethics are valuable in highlighting moral pluralism, it is essential to avoid using them to overstate the extent of cultural universals in moral outlooks by giving limited attention to ways the ethics vary in different cultural contexts.

Moral Relativism of Cultural Psychology

As attention is increasingly given to issues of social justice by theorists concerned with morality, it is important to be clear about the assumptions of the relativistic approaches to moral development associated with cultural psychology. Universalistic theorists of moral development have, in recent years, undertaken cross-cultural work as part of an effort to identify what they consider to be morally abusive cultural practices. This new direction may be seen in Turiel's 2002 volume *The Culture of Morality: Social Development, Context, and Conflict*, and in the growing number of articles on social justice by social domain theorists (e.g., Neff, 2001; Turiel, 1998, 2005; Turiel & Wainryb, 1998; Wainryb & Turiel, 1994). In articulating this type of stance, the conclusion is drawn that collectivist cultural outlooks entail the oppression of justice and individual rights: "In so-called collectivist culture, individualism is alive and well. Traditions of social hierarchy, whether in Western or non-Western cultures, embody freedom, autonomy and entitlements for those in dominant positions. Those in subordinate positions, such as women relative to men, are restricted in freedom of activity and rights" (Turiel, 2005, p. 9).

From this perspective, hierarchical social relationships are considered inherently oppressive, with power accruing to individuals in dominant positions and subjugation experienced by individuals in subordinate positions. This stance is congruent with recent directions in anthropology that embrace a universal feminism and treat culture not as a symbolic system of meanings and practices but as a vehicle for economic and political hegemony based on forces of Western imperialism and globalization (e.g., Abu-Lughod, 1993; Bumiller, 1990; Nelson & Chowdhury, 1994).

This type of viewpoint held in the distinct domain tradition is based on a view that research on morality in cultural psychology reflects an extreme moral relativism in which the fact of particular standards or practices being adopted by a particular social group confers moral legitimacy on those standards or practices. Contemporary theoretical debates on the issue of appraising cultural differences in moral outlooks have proceeded, however, using extreme examples, with issues such as widow burning, female genital cutting, and corporal punishment discussed by Turiel (2002, 2005) as evidence to support antirelativistic arguments, and similar types of issues discussed by Shweder and his colleagues (1987; Shweder, 2013, 2017) as evidence to support relativist arguments. To provide insight into this debate,

it is valuable, then, to understand more fully the assumptions of relativist work on morality in cultural psychology and to recognize that even as such work embraces moral pluralism and cultural contextualization, it does not embody the “anything goes” assumptions of extreme relativism attributed to it by critics.

Relativist positions within cultural psychology highlight the need for a greater cultural contextualization of understandings and for avoiding, on the basis of limited information, moral judgments that fail to take into account local cultural meanings. As Shweder (2012) characterizes this type of approach, its aim is “to caution against haste (rapid, habitual, affect-laden, or spontaneous information-processing) and parochialism (assimilating all new experiences to readily available local frameworks of reference) and to lend credence to the general caution that one should be slow to make moral judgments about the customary practices of little-known others” (p. 88). This type of cultural contextualization may be seen, for example, in Shweder’s explication of the background assumptions that contribute to Oriya Hindu Brahmins appraising as a moral breach an eldest son having a haircut and eating chicken the day after his father died (Shweder et al., 1987). As Shweder explains, this moral appraisal stems from the Oriyan Brahmins’ belief that the person has an immortal, reincarnating soul that can only proceed on its transmigratory journey if his family undertakes steps to remove the death pollution associated with the father’s corpse, steps that involve practices such as abstinence, fasting, and acting to keep outside pollution away from living bodies for a specified period of time.

The relativist approach associated with cultural psychology recognizes the existence of universals. For example, there is acknowledgment of empirical universals, such as the recognition that “in all cultures there [is] some perception of the self as a continuous entity in time and, as, in some sense, the same person. There [is] some kind of distinction between internal experience and external things” (Shweder & LeVine, 1984, p. 14). There is also the acknowledgment of abstract universals, including “such moral ends as autonomy, justice, harm, avoidance, loyalty, benevolence, piety, duty, respect, gratitude, sympathy, chastity, purity, sanctity and others” (Shweder, 2012, p. 98). It is further recognized, however, that these abstract universals are instantiated in culturally variable ways and are therefore compatible with marked cross-cultural differences in everyday moral judgments, and they

cannot all be maximized simultaneously, with different value trade-offs made in different situations. In this regard, for example, the death practices of the Oriyan Brahmans discussed earlier instantiate abstract conceptions of beneficence, care, and reciprocity, even as these death practices represent moral violations only among Oriyan Brahmans and not among Americans.

The cultural relativism associated with cultural psychology arrives at a position of cultural contextualization of understandings and of identification of abstract universals that underlie culturally distinctive moral outlooks. This type of relativist stance per se, however, does not address the problem of extreme moral relativism identified by critics. Whereas the relativist stance associated with cultural psychology involves expanding the range of what is considered morally acceptable, it cannot avoid addressing how to identify moral abuse. The latter type of judgment notably is made with recognition of respects in which any such judgment may not be considered an absolute truth or as a matter that can be fully defended logically or empirically. As Bruner (1990) characterizes this type of stance, “knowledge is ‘right’ or ‘wrong’ in light of the perspective we have chosen to assume. Rights and wrongs of this kind—however well we can test them—do not sum to absolute truths and falsities. The best we can hope for is that we be aware of our own perspective and those of others when we make our claims of ‘rightness’ and ‘wrongness’ ” (p. 25).

This statement by Bruner acknowledges that to avoid a morally untenable stance of extreme moral relativism, theorists must not only contextualize understandings and gain greater awareness of diverse cultural meanings and practices, but also arrive at an eventual, even if qualified, appraisal of moral rightness or wrongness. As Shweder (2008a) concludes in regard to cultural relativism, “this is not a message that must be soft on tyranny, irrationality, or arbitrary rule” (p. 378).

In summary, we have highlighted the value of appreciating that the relativism of work on morality in cultural psychology brings with it a greater effort to understand local cultural meanings, while acknowledging certain universals that reflect common humanity and common human experiences. We have also highlighted, however, the limited focus in work to date on morality in cultural psychology, on the types of judgments that, while more relativistic than the outlooks associated with universalistic approaches to morality, identify moral abuse in ways that can support social action.

FUTURE RESEARCH DIRECTIONS

Despite the growing body of work in cultural psychology on morality, cultural work on morality remains in a peripheral position in the field, with the major contemporary theories of morality both in developmental and social psychology tending to downplay cultural influences. However, as we also noted, there has been significant progress in the acknowledgment of moral pluralism, with the recognition that forms of morality exist beyond justice issues. Also, a growing but still limited body of work attempts to understand ways that moral outlooks vary in different cultural contexts. In addition to continuing to build on the types of research in cultural psychology that have already been discussed, we focus here on two examples of promising new directions for cultural research. In particular, we briefly describe research that focuses on understanding the developmental emergence of moral outlooks and research that is bringing a greater cultural awareness to work on power dynamics and intergroup relations.

Culture and the Development of Moral Outlooks

One example of a promising new direction in understanding morality is to examine the developmental emergence of moral outlooks in different cultural contexts. This topic is worthy of study given the limited attention paid in past research to cultural influences on the direction and endpoints of child development. To the extent that cultural differences are identified in adult moral outlooks, questions arise about the common and culturally variable developmental pathways through which such outlooks emerge and the ways such outlooks are cultivated through socialization (Keller, [Chapter 15](#), this volume).

Research among German infants provides evidence that young children are intrinsically motivated to help, as seen in findings that infants as young as age 14–18 months spontaneously provide instrumental aid to others (Warneken & Tomasello, 2006, 2007, 2008). This research demonstrates that offering an external incentive decreases future helping among young children. Warneken and Tomasello (2008), for example, showed that 20-month-olds who were given opportunities to help a stranger (e.g., handing a

dropped object to an experimenter), were less likely to help in a subsequent situation if they had been given a toy as a reward than if they had not been given such an external incentive.

If as this research suggests, helping may be intrinsically motivated early in development, a key question is to understand ways children's motivational outlooks may change over time as they become more responsible for complying with social expectations. Whereas young children appear to have an intrinsic motivation to help, children's prosocial motivation may shift over the course of development as they adopt contrasting culturally based outlooks on social expectations. For example, cross-cultural research has pointed to Indian adults, as compared with American adults, more fully internalizing duties to be responsive to the needs of family and friends, with Indians reporting high levels of autonomy and satisfaction in meeting duties to family and friends, and Americans associating less autonomy and satisfaction with meeting such duties (Miller et al., 2011). Research on second and fifth graders in the United States and India that assessed children's perceptions of a story in which a child helped her sibling either spontaneously or in response to being asked to do this by her parent (Goyal, Wice, Aladro, Kallberg-Schroff, & Miller, 2017) provided evidence of culturally variable moral enculturation processes. Whereas U.S. children viewed the protagonist as less strongly motivated to help in the case involving parental expectations, Indian children viewed the protagonist as having a strong desire to help in both cases, with this cross-cultural difference greater at older ages. These findings suggest that U.S. and Indian children over the course of development gradually acquire culturally distinctive outlooks on interpersonal responsibilities.

Cross-cultural developmental research also highlights ways that the same socialization practices may be associated with culturally variable moral outcomes. Comparative research on toddlers in India and Germany, for instance, has demonstrated that Indian mothers' use of punitive practices is positively related to their children's helping, but that among German mothers, it is negatively related to their children's helping (Torréns & Kärtner, 2017). Whereas children of Indian mothers who endorsed punishing failure to help were more likely to help later in a series of instrumental helping tasks, the opposite trend was observed among German mother-infant dyads.

Research on socialization processes also points to cultural groups promoting values that are integral to their distinctive moral codes. For example, cultural variation in socialization goals has been documented in the contrasting ways in which German and Indian mothers scaffold their toddlers' behaviors in response to receiving a gift (Kärtner, Crafa, Chaudhary, & Keller, 2016; Keller, [Chapter 15](#), this volume). Reflecting their emphasis on the socialization of psychological autonomy, German mothers modeled in an exaggerated way their own positive reactions to the gift. In contrast, reflecting their emphasis on the socialization of interpersonal responsiveness, Indian mothers prompted the child to acknowledge the gift giver, thus teaching the child about the importance of showing gratitude for help received (Appadurai, 1985).

In other work, empathy, which is a core aspect of moral outlooks in Japan (Shimizu, 2001) tends to be socialized in Japanese parents' everyday communication with their infants (Clancy, 2008). In contrast to the emphasis placed on the promotion of word learning in communication with infants by American mothers, Japanese mothers more commonly engage in "empathy routines" that involve prompting the infant to feel empathy and behave in prosocial ways toward other persons or objects (Fernald & Morikawa, 1993; see also Nisbett, [Chapter 7](#), this volume). This type of approach may be seen in the following illustrative example from Fernald and Morikawa (1993), in which a Japanese mother directs her infant's attention to a toy dog:

Hai wan-chan. (Here! It's a doggy)
Kawaii Kawaii shi-te age-te. (Give it a love)
Kawaii Kawaii Kawaii (Love, love, love) (p. 653)

While saying this, the mother encourages her infant to gently pat the toy dog. This type of parenting style emphasizing the socialization of empathy is also evident at older ages. For example, Japanese mothers have been observed to promote their children's empathic responsiveness by modeling their own disappointment after the child fails to meet an expectation (Trommsdorff & Kornadt, 2003), which leads the child to become sensitive to ways his or her behavior affects others and to learn the importance of *omoiyari* (empathy).

Cultural Perspectives on Power Dynamics and Intergroup Relations

Another example of a promising new research direction is to bring a cultural perspective to the examination of power dynamics and intergroup relations. This topic is particularly valuable to address given that power dynamics and intergroup relationships are approached in contemporary work in both psychology (e.g., Turiel, 2005) and anthropology (e.g., Nelson & Chowdhury, 1994) in ways that downplay cultural meanings and practices. As Shweder and his colleagues note, a return to moral universalism has come to dominate perspectives both in anthropology and psychology since the advent of global feminism and the international human rights movement (Shweder, 2012; Shweder, Minow & Markus, 2002). As Shweder observes:

Some anthropologists have even begun to look more favorably on doctrines of moral universalism, especially versions of the doctrine formulated in the language of “natural rights” or as a part of a moral critique of patriarchy aimed at liberating women (and children) and cleansing the world of so-called oppressive or harmful cultural practices: bride-price, polygamy, female genital surgery, child labor, arranged marriage, the sexual division of labor in the family, and “veiling” might be examples of customs disfavored by contemporary versions of moral universalism within the profession of cultural anthropology. (Shweder, 2012, p. 88)

In an emerging body of work, researchers in cultural psychology, however, are highlighting the need to give more attention to ways such everyday practices may be experienced as culturally valued, even as they violate Western liberal cultural outlooks that privilege equality and individual rights (Minow, Shweder, & Markus, 2008; Shweder, 2008b; Shweder et al., 2002). In research examining the everyday lives of Hindu Indian women from the old temple town of Bhubaneswar, Menon and Shweder (1998) highlight respects in which the women experience their everyday lives as fulfilling, even as they live in a community that does not privilege liberty and equality—central values of liberalism. According to anthropological feminist accounts (e.g., Kondos, 1989; Raheja & Gold, 1994), the family life of Indian women constrains and restricts individual freedom, with the women seen either as passive victims of an oppressive system or as rebels acting to resist the oppression of their everyday lives. However, Menon and Shweder (1998) argue that such conclusions fail to

account for local cultural meanings and practices that contribute to women experiencing agency in their family roles (for a discussion of conceptions of agency, see Markus & Hamedani, [Chapter 1](#), this volume). In the case of residents of Bhubaneswar, women are shown to view their family roles as meaningful and important, in working to achieve spiritual refinement through fulfillment of family duties. The values of self-discipline, self-control, loyalty, patronage, protection, and sacrifice are shown to be the most prized moral goods in this community. The women are aware and proud of their traditions, and seek to preserve them rather than rebel against or resist them (Menon, 2013). Notably, in a position that rejects extreme relativism (Menon, personal communication, April 24, 2017), Menon argues that in India, acts such as dowry murders and rapes need to be recognized as crimes deserving of punishment and should not be interpreted as supporting a conclusion that misogyny is emblematic of the larger culture. However, Menon (2013; Menon & Shweder, 1998) also argues that for public policy interventions to be successful, they must be framed in ways that are congruent with the beliefs, values, and practices of the society, with the recognition that Western feminism's failure to mobilize large numbers of Hindu women may lie, at least in part, in its promotion of outlooks that are insensitive to local cultural sensibilities.

In another illustration of work on this topic, studies have examined the roles of husbands and wives in different cultural contexts. In work from the distinct domain perspective, Neff (2001), for example, has argued that an asymmetry of rights and duties exists within family roles in India. In her research on married couples in Mysore, India, responses to a vignette depicting a marital conflict revealed a greater concern for issues related to autonomy in cases involving husbands as compared with wives. Neff interpreted such results as providing support for an imbalance in the rights and duties that exist within Indian families; she further concluded that this signifies that relationships structured by hierarchical gender norms are unjust and oppressive. However, research by Goyal, Wice, Adams, Chauhan, and Miller (2015) has challenged these claims. Through an analysis of real-life, everyday conflicts between husbands and wives in U.S. and Indian families, Goyal and her colleagues demonstrated that Indian participants view the family responsibilities of husbands and wives as differing in kind, which calls into question the experimental treatment of such roles as totally

reversible in the research by Neff (2001). Furthermore, Goyal and her colleagues found that, as compared with U.S. couples, Indian couples appraised the scope of the role-related duties of husbands to be as great as that of wives. Such findings challenge the notion of an imbalance in duties associated with female as compared with male roles (see also Menon, 2013). Similar trends were observed in a comparison of gender roles and perceptions of feminism among middle-class women in the United States and Japan (Schaberg, 2002); Japanese women showed a greater endorsement of hierarchically structured reciprocal family roles in marriage than did U.S. women.

Finally, an additional, related issue of importance is to examine respects in which dissent is expressed against cultural practices in all cultural communities, with this dissent framed in ways that take into account local cultural meanings and practices. Such a trend is illustrated in the example of an adolescent son in a Brahmin family, who temporarily stopped wearing the holy symbol of the Sacred Thread (Much, 1997). The son's reported motives were to challenge the moral meanings given to that symbol and to express his personal view that wearing such a symbol represented merely a social convention rather than a moral duty. However, in framing dissent in this way, the son did not call into question more fundamental commitments of his cultural community to the principle of hierarchy and to caste identity. In another example, Schaberg (2002), making this same point, uncovered respects in which women both in the United States and Japan endorse certain common aspects of feminist outlooks, including enhanced opportunities for women in the workplace, even while the form of feminism held by U.S. women places a greater stress on values such as gender equality, and that held by Japanese entails commitments to larger societal change, beyond issues involving gender, as well as a greater focus on viewing society as a network of interrelated human beings rather than as separate groups with their own interests.

CONCLUSIONS

Research on moral development in cultural psychology highlights the need to make theories of morality more culturally pluralistic and to pay more

attention to the role of everyday cultural contexts in affecting moral outlooks. Rather than leading to an extreme form of moral relativism, work in this tradition underscores the importance of becoming more aware of one's own cultural biases and of appraising alternative cultural commitments in ways that are appreciative of their coherence and sense. Taking into account a wider range of moral concerns and increasingly addressing real-world applications, work on moral development in cultural psychology underscores the inseparable interrelationships between culture, morality, and lived experience.

CHAPTER 17

Food and Eating

Paul Rozin, Matthew B. Ruby, and Adam B. Cohen

Food and eating are central to human life in terms of time and money spent, and importance in human biological and cultural evolution. Food is also a foundational system in which adaptations arise and are then exported via preadaptation to other domains, such as social relations and religion. Because humans are omnivores, enculturation and learning are the primary forces that generate food preferences, attitudes, and rituals. While some human preferences, such as the desire for sweet tastes, have a biological origin, others, such as the preference for spicy foods, reverse biological predispositions. Culture is a powerful force shaping the food domain, as evidenced by the widely varying cuisines in different countries. Food is an important part of the social world and religion. In the modern, developed world, many of the adaptations to the ancestral environment, such as the preferences for fat and sugar, have become maladaptive. Cultural adjustments to this change are incomplete. France has adjusted better to these changes than has the United States. In the modern omnivore's dilemma, concerns about sustainability enter into considerations about food, such as concerns about consuming meat. There is a new moral force operating in the food domain. We understand very little about how enculturation to cuisine occurs, how preferences and attitudes toward food develop, and the details of how to eat are instilled in children. Given the importance of food, it is surprising how little attention it has received in psychology.

Food and eating are central to human and animal life. Food choice is a major force in biological and cultural evolution. Food and eating, including shopping (foraging) and food preparation, occupy a substantial amount of time in the waking day of humans. Food is a distinctive feature of cultures, as evidenced by discussions of cuisine and restaurant lists in travel books,

and the enormous variety of ethnic cookbooks. Food typically plays a central role in celebrations, such as marriage, and often in religion. Nonetheless, unlike the neighboring disciplines of anthropology and zoology, in which food is a central focus, food and eating have received little attention in the various branches of psychology. This is at least in part due to the process as opposed to domain organization of psychology (P. Rozin, 2006b). We attempt in this chapter to organize what we know about food and eating, from a cultural perspective. We believe food and eating should be a major concern for cultural psychology, both as a central domain of human life, a foundational system that extends into other domains, and as a route to understanding other areas, including social organization.

Of course, the large number of cookbooks representing the cuisines of different areas of the world illustrates a critical part of food and culture, but we do not list them here. We provide here a set of references to orient the reader to what is known about food in a cultural context: from the anthropological and/or evolutionary perspective, De Garine (1972), Diamond (1996), Harris and Ross (1987), Katz (1982), E. Rozin (1982), and Wrangham (2009); from the ethnographic perspective, Meigs (1984), Ohnuki-Tierney (1993), and Whitehead (2000); from a sociological perspective, Beardsworth and Keil (1996) and Maurer and Sobal (1995); from a psychological perspective, Shepherd and Raats (2006), Prescott (2012), and Spence and Piqueras-Fiszman (2014); and from an evolutionary perspective, P. Rozin and Todd (2015). A cultural–historical perspective is offered by Kass (1994), Levenstein (1993), Simoons (1991), and Whorton (1982). There are a few books that provide a broad, general perspective, including Barker (1982), Beardsworth and Keil, (1996); Fischler (1990), Katz (2004), Kiple and Ornelas (2000), Meiselman (2000), and Anderson (2014). There is a series of books about food and culture (series edited by K. Albala), with individual books on food and culture for many countries (e.g., India; see Sen, 2004).

THE FOOD–EATING DOMAIN

Food involves one of the basic domains of survival. It is central in animal life: Food search, identification, and ingestion probably accounts for most of

the waking time of most animals. Food selection is one of, perhaps *the* single most important force in animal evolution; if you want to know as much as you can about an unknown animal, the best thing to ask, other than its phylogenetic classification, is “What does it eat?” (P. Rozin & Todd, 2015). This single fact is highly informative about the sense organs, physiology of the digestive system, motor abilities, and learning or cognitive capacities. Animals that eat a very narrow range of foods are highly tuned to detect and appropriate their prey: Examples are anteaters, the carnivorous mammals, and specialized herbivores, such as pandas and koalas. More generalist animals have a broader but less specialized set of skills and structures, and are generally more well developed in what we loosely call “intelligence.” A generalist animal faces a great set of challenges: to find combinations of foods that are nutritive, balanced, and minimally toxic. So, a first reason to be interested in food in cultural psychology is that it is such an important part of our primate heritage, and it is closely linked to intelligence and social interactions.

A second reason is that food is one of the major sources of affect. Eating is at the same time satisfying and threatening. It is a necessary and frequent part of remaining alive. However, many of the possible edibles in the world are toxic or vehicles for dangerous microorganisms. People (and other animals) feel very strongly about what goes in their mouths; they are rarely neutral on this point. For humans, there is another dimension that amplifies the affective response to foods. It is widely believed in traditional cultures that a person takes on the properties of the foods he or she eats (“You are what you eat”). In this context, eating can have moral import, and can be believed to affect personality, and a person’s fortunes. “You are what you eat” is an eminently sensible idea; when we mix two things (in this case, a person and the food he or she eats), it is natural to believe that the product reflects both of the constituents. Although modern biological science makes clear that there are no grounds for believing that properties such as moral status or personality could be transmitted by the molecules that result from the process of digestion, it has been shown that even educated Westerners believe, implicitly, that one takes on the properties of what one eats (Nemeroff & Rozin, 1989).

There are other arguments for a cultural psychology of food and eating that derive directly from human issues, and human culture. Food selection

and procurement figure prominently in almost all theories of the evolution of humans. First, there was a shift from a more plant-dominated forest diet to a diet with more animal protein in the savannah environment. Animal foods are generally harder to procure, so that more demands are made on motor capacities, sensory abilities, and cognitive/social processes, but a diet relying on animals does relieve a creature of the risks of dietary imbalance. All animals are made of roughly the same molecules, so almost any animal is a good source of nutrition. This is less so for plants, which are often incomplete or imbalanced sources of nutrients for animals. For the human omnivore, seeking animal food but still consuming a wide range of plant foods, there are two challenges: procurement of food (most challenging for animal prey) and appropriate food selection (more challenging, the more the reliance on plant foods).

Second was the taming of fire, and the associated origin of cooking (Wrangham, 2009). Cooking increased the digestibility of many energy rich foods and also served as an effective way of killing microorganisms in the food. Third was the development of agriculture and domestication (Diamond, 1996). This development, made primarily some 4,000 to 10,000 years ago, provided humans with a steady and efficient food supply. This allowed for larger aggregations of humans, and for the specialization of labor inside and outside the food domain that prompted all sorts of technological advances. So food, in the evolution of human culture, provides a critical opportunity for extended development of other domains of life, including all sorts of crafts, aesthetic practices, morality, social organizations, religion, and high technologies (Diamond, 1996).

In contemporary human life, work and food-eating are usually the two major categories of waking activities. Activity logs from 14 cultures, painstakingly documented by Szalai (1972), reveal that (for three cultures that we have tabulated: Peru, the United States, and France in the late 1960s or early 1970s, food at 13% of total time (including food-related activities: eating, shopping, preparation, cleanup), is third behind sleep (37%) and work (16%). More recent data from activity records kept by individuals in France and the United States, along with tabulation of some prior data on time spent in different activities from the two countries, indicate that eating occupies 5–7% of waking time in the United States, and 11–14% in France (Krueger et al., 2009). Furthermore, much of work is devoted to earning

money or trade that is ultimately spent on food. Indeed, in most developing countries, food is the principal source of expenditures, amounting to over 30% of total expenditures (Table 17.1). The economic importance of food is itself a major cultural variable.

TABLE 17.1. Food Expenditures in Selected Countries with Populations Greater Than 50 Million (In Order of Increasing Percent of Total Expenditures)

Country	% of expenditures consumed on food at home ^a	Total consumer expenditures per person (\$)
United States	6.6	36,300
United Kingdom	8.6	28,417
Germany	10.2	24,677
France	13.3	23,763
Japan	14.1	21,427
Brazil	15.6	7,111
Turkey	21.6	7,564
Mexico	23.3	6,934
China	25.5	2,794
Russia	28.4	7,225
India	30.7	983
Indonesia	33.1	2,005
Pakistan	41.4	1,082
Nigeria	56.6	2,227

Note. The data were computed based on Euromonitor International data extracted August 2016. Source: Economic Research Service, U.S. Department of Agriculture calculations based on annual household expenditure data.

^aPercent of total spending devoted to food at home.

There are further, discipline-related reasons that make the study of food of particular interest to psychologists in general, and to cultural psychologists in particular. First, food is a major subject of thought, because the need for it is so compelling, and obtaining it is often challenging. It is therefore likely that many of the features of intelligence, so important for humans, arose first in solving problems in the domain of food. “What is edible and what is not” is one of the most critical problems facing the

human omnivore (P. Rozin, 1976). Powerful, plastic adaptations to discover the effects of ingested food (e.g., conditioned taste aversions) stand out among learning abilities, and use of food as reinforcement is the central technique of the psychology of learning. More recently, in research on primate cognition, food choice is the dominant means for testing capacities (reviewed in Santos & Rosati, 2015). Siegal (1996) has argued that in child development, the first domain in which nascent intellectual abilities appear often concerns food and the detection of toxicity. Similarly, there are instances in primate cognition work (e.g., the endowment effect) where something can only be demonstrated in the domain of food (reviewed in Santos & Rosati, 2015). The search for food is central to the foraging literature, which has demonstrated exquisite and precise decisions as to when to abandon particular foraging sites, food selection within a site, and so forth (summarized in P. Rozin & Todd, 2015). There is even evidence that the way two different species of monkeys differ in response to spatial or temporal distance to food reward (temporal or spatial discounting) relates to their mode of foraging (reviewed in Santos & Rosati, 2015). Second, food and eating are most influential among our basic biological systems with respect to shaping human culture. The other systems, including breathing, excretion and sex, maintain much of their nonhuman primate character even in elaborated human cultures. The cultural elaboration of food and eating is the subject of Leon Kass's (1994) remarkable book, *The Hungry Soul*, in which he documents the transformation of food and eating from a source of nutrition to a socially meaningful substance, from primate origins through European history. As Kass notes, "An activity that is inherently ugly is beautified by graceful deed and tactful speech. An activity that is violent and destructive is tamed by gentle manner that keeps its destructive character mostly out of sight. An activity that deforms and dissolves living forms is given form-ality of its own by the work of the human intellect. . . . We eat as if we don't have to, we exploit an animal necessity, as a ballerina exploits gravity" (pp. 154, 158).

Third, a remarkable thing has happened regarding food in the developed world toward the end of the 20th century. Technological advances have virtually inverted our food environment, so that our adaptations to our ancestral environment are now often maladaptive (e.g., sweet preference; P. Rozin & Todd, 2015). In addition, in the later 20th century, ethical issues

became prominent in developed cultures, with concerns about the consequences of eating and food choice for human welfare, animal welfare, and the planet. Sustainability is a rising concern in wealthier countries. We discuss these aspects of the modern world in a later section.

THE ECOLOGY OF FOOD AND EATING, AND MAJOR DIMENSIONS OF CULTURAL PSYCHOLOGY

The fundamental role of food in cultural evolution causes it to play a major role in shaping thinking and behaviors in many domains, accounting for both cultural universals and distinct, major cultural differences. The holistic–analytic dimension, related to the interdependence–independence dimension, has been a dominant theme of cultural psychology. Varnum, Grossmann, Kitayama, and Nisbett (2010) have argued that the social orientation dimension (interdependence–independence) has temporal priority to, and is in part causal, for the cognitive holistic–analytic dimension. The origins of the social orientation differences have been linked to food ecology differences. Talhelm et al. (2014) have presented evidence that rice-based subsistence promotes interdependent (collectivist) social orientations, while wheat-based subsistence promotes independent (individualist) social orientations. Cultivation of the principal food staple (rice or wheat) creates different demands for cooperation, with rice growing requiring much more communal action. Talhelm et al. demonstrated that the more southern regions of China, with a rice-based food system, show more collective/interdependent tendencies than the northern regions of China, which rely more on wheat. They argue that this correlation cannot be attributed to climate differences, because the rice–collective link appears in regions of China that are geographically and climatically very similar to other regions that show a wheat-based individualistic orientation. While the great majority of people on earth show a more collective orientation, individualism predominates in Western Europe and North America, where wheat is the predominant staple grain.

Similar types of food–ecology arguments are suggested to account for differences in the culture of honor. According to Nisbett and Cohen (1996),

a culture of honor is promoted by cattle, sheep, and pig raising, as opposed to farming. The vagueness of the borders of individuals' ranges and the threat of theft require more border patrolling and aggression toward intruders, and so creates a cultural premium on the defense of one's honorable reputation.

These two lines of work highlight the importance of cooperation as a variable in different types of grain production, and the importance of confrontation dependent on reliance on animal versus plants as the major source of nutrition. "Modernity" itself seems associated with individualism, and modernity is also associated with a substantial reduction in the economic importance of the food system (see [Table 17.1](#)).

CUISINE

Cuisine is one of the major distinctive manifestations of any culture. We can use the word *cuisine* to represent the body of shared rules, beliefs, and practices relating to food within any culture. Regularities are sufficiently great within cultures that we can usually identify the culture by examining what is eaten. The abundance of ethnic cookbooks, the space devoted to cuisine in travel books, and the centrality of food in ethnographies all testify to the importance of cuisine as a cultural "marker."

Eating involves incorporating substance; humans typically do something to the things they find in the world before consuming them. Some of this amounts to physical preparation, such as peeling or cutting, but much of it involves more elaborate transformations, including mixing, grinding, cooking, and flavoring. These behaviors, conveniently, often leave substantial records that can be examined by archeologists.

At the level of the "dish," Elisabeth Rozin (1982) points out that there are three components: the staple foods, the processing techniques, and the flavorings. She notes that most cuisines add a particular set of flavoring ingredients to most savory dishes, and calls these "flavor principles." Thus, Southern Italian cuisine is characterized by tomato, sweet pepper, olive oil, and oregano as flavorings; Chinese cuisine typically flavors with soy sauce, ginger root, and rice wine; and Mexican cuisine characteristically uses chili pepper with either lime or tomato. Flavor principles provide a distinct

identity to the foods of a particular group, and offer a sense of comfort and familiarity. They may also serve as a means to introduce a new staple food into a cuisine, by making it taste familiar via the traditional flavor principle (E. Rozin & Rozin, 1981). The meal is another component of cuisine. Meals have an internal structure, varying from a single dish of combined ingredients to sequences of foods, as in the appetizer–entrée–dessert sequence common in many Western cuisines (for an analysis of the British meal, see Douglas & Nicod, 1974). In many traditional cultures, the various meals are similar in content and structure, with breakfast as warmed-over last night’s dinner. In many Western cultures, a separate first meal, breakfast, has its own foods and flavors. Howard Schutz (1989) has pointed out that cultures have “appropriateness” rules, having to do with what foods can be mixed or eaten together, proper sequences of foods, and foods for particular times or occasions.

The social eating situation is another aspect of cuisine. There are issues of who eats with whom, order of eating (e.g., children or esteemed older relatives first), rules for leaving the table, and rules for what is supposed to be discussed during the meal (or what is distasteful to discuss). A final aspect of cuisine is the manner of food consumption. Cultures vary markedly on this point. For example, the principal means of conveying food to the mouth is the right hand in South Asia, chopsticks in East Asia, and spoons and forks in most of the Western World (B. Wilson, 2012).

THE BIOLOGICAL FOOD SYSTEM: THE HUMAN GENERALIST AND SOME FOOD UNIVERSALS

The biological/evolutionary foundation for food choice has been emphasized by evolutionary anthropologists (e.g., Harris & Ross, 1987), and is presented in a chapter in the *Handbook of Evolutionary Psychology* (P. Rozin & Todd, 2015). We summarize it briefly here.

The food generalist faces a daunting food choice problem (P. Rozin, 1976). Obtaining adequate nutrition involves satisfying the body’s persistent need for some 40 nutrients, including water, essential amino acids, some fatty acids, vitamins, and minerals. In the course of satisfying these nutritional needs, the generalist must also attain adequate energy from a

mixture of proteins, fats, and carbohydrates. This set of nutritional requirements can be met easily if there is a fair amount of animal food in the diet, or by choosing a broad diet among plant foods. However, the generalist faces a dilemma, because in the course of sampling the potential food environment widely, one is likely to encounter potential foods with toxic components or harmful microorganisms. The former are more likely in plants; the latter, in animal foods. The risks of eating broadly are high, as are the benefits resulting from the ability to survive in diverse environments. There are no simple ways to reliably avoid toxins and infective agents on sensory grounds, or to avoid potential foods that have minimal nutritional value. For the most part, this must be learned, and hence falls in the domains of development, cultural traditions, and the acquisition of culture.

However, there are some important inherited adaptations that help humans and other food generalists. There are innate biases, present at birth, to consume energy-rich foods, manifested as a preference for sweets (linked to carbohydrate content; Steiner, 1979) and fatty textures (linked to fat content). The combined sweet and fat preferences result in strong human adult preferences for mixtures of the two (Drewnowski & Greenwood, 1983). Finally, a bitter detection system allows for an innate rejection of entities that include common natural toxins.

Sensory biases do not exhaust the innate behavioral repertoire of the generalist. It is in the nature of the generalist to be both interested in and cautious about new potential foods, since they may be new sources of nutrition, but also may be toxic or infected. This combination of risks and benefits manifests (in rats and humans, where it has been studied most) in an interplay between fear of the new (“neophobia”) and attraction to the new (“neophilia”). What is familiar is safe, but it restricts the nutritional horizon in ways that may be maladaptive, because diversity in diet is healthy and allows adaptive responses to environmental changes. A common “solution” to this generalist’s or “omnivore’s dilemma” is the cautious sampling of potential new foods.

Finally, there is a set of adaptations to aid the generalist in discovering the nutritional consequences of things ingested. The basic problem is the long delay between ingestion of a food and its metabolic consequences. Conditioned taste aversions are an unusual type of learning that lead to rejection of foods that induce nausea, delayed up to a period of hours

(Garcia, Hankins, & Rusiniak, 1974; P. Rozin & Kalat, 1971). There is a corresponding, usually weaker ability, to associate tastes with delayed positive (nutritional) consequences in mammals (Sclafani, 1999).

One cannot help but be impressed by the enormous variety of the foods and eating patterns across humanity. Indeed, there would be no appeal of ethnic cuisines if we all ate the same things in the same ways. But general metabolic requirements and inherited behavioral biases do result in a substantial number of food/culinary universals or near universals in humans. One should also be open to considering *near* universals, as human ingenuity has allowed the habitation of very inhospitable environments, like the Arctic, which severely constrain nutritional options.

Humans almost always eat rather energy-rich foods in concentrated periods of time, called “meals” (Pliner & Rozin, 2000). The availability of animal foods, and elaborate preparations of foods, encourage organization of eating in terms of meals. Most human beings consume some combination of plant and animal foods. In most cultures, men are more involved in the procurement of animal foods, and women in the procurement of plant foods and in food preparation. Meals are usually a social occasion. Sharing of food is a form of bonding throughout the world; one shares food with those with whom one is close, and this sharing (“shared substance”) reinforces the closeness. Thus, food is interpersonally important. Although, to some degree, foods are consumed raw in all cultures, there is some processing of many foods before ingestion. This includes physical changes (removing shells, grinding), mixing of foods, and cooking. The cuisines characteristic of particular cultures, not surprisingly, involve combinations of ingredients and their processing to meet human nutritional needs (Katz, 1982).

THE CULTURAL TRANSFORMATIONS OF FOOD AND EATING: PREADAPTATION AND THE FUNCTIONS AND MEANINGS OF FOOD IN A CULTURAL CONTEXT

Leon Kass (1994) captures the major transformation in eating by humans with the contrast between the German verbs *fressen*, used for eating by

animals, and *essen*, for eating by humans. Unlike almost all other animals, humans bring food to their mouth rather than bringing their mouths to the food. As far as we know, humans alone eat using implements, have table “manners,” engage in complex social/informational exchanges during eating (at meals), elaborate foods extensively before eating them, and eat foods in specific orders. In short, eating is an expression of human civilization. Food has become much more than nutrition.

As noted earlier, food stands out among the biological domains in the degree to which it has been transformed culturally. “Preadaptation” is the process that accounts for the expansion of the food domain in the history of human cultures. Preadaptation was appreciated by Darwin (1872/1965), and has been expressed in fuller form by some more modern evolutionists, particularly Bock (1959) and Mayr (1960). It involves the use of an already existent (usually evolved) structure for a new purpose. According to Mayr, preadaptation is the main source of evolutionary novelties and the principal process in speciation. It essentially involves a recombination of existing structures and genes rather than creation of new genes by mutation.

One of the finest examples of preadaptation has to do with the food system. The mouth, with its elaborations of teeth and tongue, is an aperture designed to take in nutrients (and air). Clearly, the tongue and teeth have evolved to facilitate the processing of food. But in human evolution, the teeth and tongue, and the entire oral cavity and its link to the respiratory system, are utilized by the language system for the expression of speech. Teeth and tongue were preadapted for speech and were opportunistically used by the speech system. To take another example, a good argument can be made that the species of plants and animals that were domesticated thousands of years ago were selected by humans because they were preadapted, in terms of social organization, mode of reproduction, and so forth, to be useful to, and manageable by, humans (Diamond, 1996).

Preadaptation plays an even more striking role in cultural evolution than in biological evolution (P. Rozin, 1999a). This is because variation in cultural evolution can be directed by purpose, while in biological evolution, the occurrence of variations is dependent on random processes. If a cultural tradition, practice, artifact, or institution might be adaptive in a new context, it can just be transplanted. Thus, one can combine the virtues of the

calculator and typewriter and create a computer, or apply a culinary technique discovered in one culture to another.

The expansion of food from nutrition to a complex expression of civilization (Kass, 1994) by preadaptation has taken place along a number of lines, presumably to different degrees and in different temporal orders of cultural evolution in different cultures (Figure 17.1). Early in human evolution, food became an entity of social significance. The meal became a center for social interaction. Food became central to important cultural events. Food sharing became an explicit and implicit form of expression of interpersonal intimacy. Food became a marker of the status of the individual (as in the Hindu caste system, or the public consumption of expensive foods) and a form of group identity. Note the pejorative descriptions of British sailors as “limeys,” Germans as “krauts,” and French as “frogs.” Food enters the aesthetic domain, as cuisine, taking its place next to other human activities with lesser links to our fundamental biology, such as literature, music, and art. Cuisines elaborate the flavors, the presentation of food, and the serving and eating of food in ways that can hardly be described as motivated by improved nutritional properties. Rather, it is appeal to the palate and the eye.

FIGURE 17.1. Food preadaptation.

Food becomes an integral part of the moral/religious domain, for example, when it is used in religious ritual (e.g., taking the host in the Catholic church, the Jewish laws and traditions of *kashrut*). Among Hindu Indians, who comprise more than 10% of the world’s population, food can be considered a form of “moral currency”; Appadurai (1981) described it as a “biomoral” substance. The caste system ranked people according to moral

purity and has become less important in recent decades. Caste was largely defined and defended in terms of food transactions, which prevented the food of those less morally pure from being consumed by those higher in the system (Marriott, 1968). In the West (e.g., the United States), the moral role of food is muted, though overeating, fast foods, fatty foods, and most clearly cigarettes, have come to take on moral overtones for some (P. Rozin, 1999b; Ruby, 2012; Stein & Nemeroff, 1995; Vartanian, 2015).

In addition to expanded roles for food as art form, moral, and social vehicle, the vocabulary associated with food is co-opted as a means of describing things that have nothing to do with food; that is, food has a metaphoric function. In fact, food is one of the major sources of metaphor (Lakoff & Johnson, 1980), such as when we say, “Janet is *sweet*,” or “Let’s get to the *meat* of the paper.” Metaphor is, of course, a quintessential example of preadaptation: export of a word from its original context to other contexts.

Because of its centrality in life, and because it is incorporated into the body, food is a major source for symbols and metaphors. The Jewish Passover celebration and the Catholic mass both use food to explicitly represent nonfood events. Rice plays a central role in Japanese life and thought, over and above its nutritional importance (Ohnuki-Tierney, 1993). Food is at the center of many rituals and taboos, many of which seem to serve functions outside the domain of nutrition (Douglas, 1966). Recently, an attempt has been made, in a systematic way, to demonstrate what it would mean to say that *X* is a symbol for *Y*, using the example of meat (*X*) as a possible symbol for maleness (*Y*) (P. Rozin, Hormes, Faith, & Wansink, 2012). Six different measures, two implicit, one explicit (rating maleness of foods), free associations, food preferences, and linguistic information all point to a relation between meat and maleness.

DISGUST AS AN EXAMPLE OF PREADAPTATION AND THE CULTURAL ELABORATION OF A FOOD- BASED SYSTEM

Disgust is a “basic emotion” (Ekman, 1992). Along with other basic emotions, disgust has three properties: (1) a particular hardwired pattern of expression, which has the function of expelling mouth contents, along with

a communication value (e.g., “Don’t eat this”); (2) a psychophysiological response, in this case nausea, which is quite specific and serves to inhibit ingestion; and (3) a behavior, withdrawal. All three of these components clearly serve the purpose of rejecting foods, which suggests that the food system constitutes the origin of disgust (see P. Rozin, Haidt, & McCauley, 2018, for a more detailed discussion of disgust). In many mammals and newborn humans, a facial expression like that of disgust is elicited by bitter tastes. The bitter rejection face and system seems to be the preadapted basis for the elaboration of disgust.

The elicitors of disgust in humans include a wide range of events, only a minority of which can be traced to food. Elicitors include contact with death or filth, many body products, disliked individuals, and the experience of certain immoral activities (e.g., incest, or child molestation). One account for this expansion is based on preadaptation in cultural evolution (P. Rozin & Fallon, 1987; P. Rozin, Haidt, McCauley & Imada, 1997; P. Rozin, Fischler, Imada, Sarubin, & Wrzesniewski, 1999; P. Rozin et al., 2018). In this view, while the meanings and elicitors of disgust expand, the basic program (expression, behavior, physiological response) remains roughly the same.

In the posited first stage (see [Figure 17.2](#)), the bitter rejection system is preadapted for rejection of foods, not because of sensory properties but because of the nature or origin of the food (P. Rozin & Fallon, 1987). A particularly interesting feature of this ideational disgust, or “core disgust,” is that the elicitors (but not bad tastes, e.g., bitter) are “contagious”; that is, they follow the sympathetic magical law of contagion: “Once in contact, always in contact” (Frazer, 1890/1922; Tylor, 1871/1974; Mauss, 1902/1972; P. Rozin & Nemeroff, 1990). If a disgusting potential food (e.g., a worm or cockroach) touches an otherwise edible entity, it renders it inedible, and, in fact, disgusting. The contagion property appears to be universal among adult humans, but it is absent in animals or in children below about 4 years of age. It seems to be a universal cultural acquisition, perhaps supported by its adaptive advantage in discouraging consumption of infected foods. It is notable, as Angyal (1941) pointed out, that almost all core disgust foods are of animal origin. It is these same foods that have the highest risk of transmitting infectious agents. The existence of contagion and the focus on animals in disgust, plus other evidence, have encouraged some scholars to identify what P. Rozin and Fallon (1987) call core disgust as “pathogen

avoidance disgust,” and to propose that this first phase of disgust is biologically evolved (Curtis, 2013; Tybur, Lieberman, Kurzban, & DeScioli, 2013).

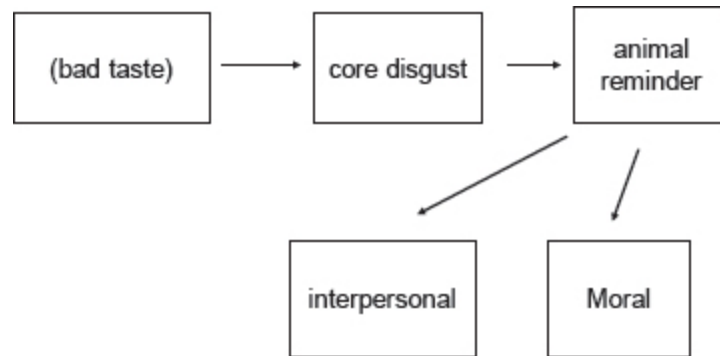

FIGURE 17.2. Preadaptation: Cultural evolution of disgust.

Feces appears to be a universal core disgust substance. Of interest, it does not qualify as an innate distaste, because it is not rejected by infants, or by most animals (P. Rozin, Hammer, Oster, Horowitz, & Marmara, 1986b). Rather, it is a universally acquired human disgust, with its own fundamental developmental concomitant, toilet training. It is proposed that disgust is co-opted as a cultural tool, to establish culturally supported aversions or prohibitions, by endowing the relevant objects with disgust properties. If a forbidden entity becomes disgusting, it will be naturally avoided, and no rules or formal punishments need be invoked. Such is clearly the case with the outcome of toilet training. By this account (P. Rozin, Haidt, & McCauley, 1993; P. Rozin et al., 2018), the range of disgust expands from its initial food base to include three other categories of events or elicitors. First, following the focus on animal foods, it is extended to a wide range of features that humans share with other animals. It is a frequent theme in cultural narratives, rituals, and beliefs that humans are not animals, but are superior to animals. Any reminder of the animal nature of humans then becomes undesirable. There is evidence that one animal feature, mortality, is a particularly important component of animal reminder disgust. The rejection of animal reminders fits with the nature of the civilizing process, as described by the distinguished culture historian Norbert Elias (1939/1978):

“People in the course of the civilizing process, seek to suppress in themselves every characteristic that they feel to be animal” (p. 120).

The expansion of disgust (P. Rozin et al., 1993, 2018) elicitors extends to unfamiliar people (“interpersonal disgust”), which probably has the adaptive value of strengthening ingroup connections and weakening those with outgroups. The alternative account (Tybur et al., 2013) can also subsume this as a form of pathogen avoidance, with less adaptation to the microbes of other groups. The pathogen account has the advantage that it can explain what has been called core, animal-reminder, and interpersonal disgust with a single motive (Tybur et al., 2013). However, it is hard to deny that disgust may also serve as a means of denying mortality and strengthening ingroup bonds.

Finally, disgust is used, to one degree or another, depending on the culture, to support moral principles. Disgust may be engaged to reinforce a cultural-based prohibition. The degree to which this occurs seems to be related to the type of moral system. Following on the work of Shweder, Much, Mahapatra, and Park (1997) on culture and moral taxonomies, disgust seems to be tied primarily to the divinity, as opposed to autonomy or community moral realms (P. Rozin et al., 1999). A comparison of the status of disgust in the United States and India is instructive. Disgust as a moral emotion is more prominent in India, because divinity morality is more important there.

In an alternative account (Tybur et al., 2013), there are three categories of disgust: pathogen avoidance, mate selection, and morality; moral, in this system, is not limited to divinity violations but includes the full range of moral violations. The nature of the mapping of disgust onto morality is still uncertain. William Miller, in *The Anatomy of Disgust* (1997), provides a rich description of the elaboration of disgust in Western cultures.

By the same process of preadaptation that expands disgust elicitors in cultural history, the process of contagion is carried along with the new elicitors. Thus, contact with an immoral person shows contagion properties (Nemeroff & Rozin, 2000).

CIVILIZED EATING

One of the most striking things about the food world, varying a great deal across cultures, is the etiquette of eating, or table manners. As Kass (1994) and Elias (1939/1978) point out, the meal is one of the special areas in which humans display and celebrate the fact that they are civilized. Almost all contemporary adult humans do not eat like animals. They sit at tables, use utensils, respect and do not touch the food on the plates of others, refrain from calling attention to their bodily functions while eating, and observe complex rules of social interaction. Civilized eating is highly complex and requires great skill. In civilized eating, the biological aspects of eating are suppressed. Kass (1994) provides a particularly graphic illustration of food, disgust, and civilization. In a typical meal situation in many cultures, individuals face each other while eating. They place food into their mouths, the interior of which is regarded as disgusting by others. Furthermore, the mass of chewed food in the mouth is itself disgusting (both interpersonally, and because of its involvement with body secretions). Remarkably, due to the virtuosity of eating as informed by table manners, this exchange goes on face-to-face, without either partner being exposed to any disgust stimuli. More remarkably, the individuals are often conversing while eating, using the same hole to speak that they use to ingest food; still, neither the inside of the mouth nor the ingested food are seen by the partner! The learning of table manners by children is surely one of the more difficult aspects of growing up.

All of these civilizations of the daily meal are yet more elaborated in special food occasions, such as eating at restaurants, feasts, dinner parties, or weddings (Kass, 1994), and the etiquette and subtle meanings of eating are particularly elaborated in Hindu Indian culture (Khare, 1976). Disgust can reasonably be described as the emotion of civilization.

CULTURE AND BIOLOGY: SOME FOOD CASE HISTORIES

Following on the interactions of biological and cultural evolution in the understanding of disgust, we now briefly consider the history of some human foods to illustrate how biological, cultural, and psychological factors

interact in the cultural evolution of foods (see P. Rozin, 1982, for a more systematic discussion of this issue).

Sugar

The history of sugar is a paradigmatic illustration of how a simple biological predisposition, the preference for sweet, is amplified and elaborated by culture (P. Rozin, 1982). The innate sweet preference encourages the search for this stimulus, and learning about where and when it may be found. In humans, in conjunction with the development of agriculture, the desire motivates the cultivation of some crops, primarily ripe fruits, sugar beets, and sugar cane, which provide this desirable taste experience. Much later in human history, the technology to extract the source of sweetness, sugars, allows for the experience of an even more desirable sweet experience.

The search for a source of easily extractable sugar (sugar cane) was a main motivation for the colonization of the tropical Americas by Europeans, and the availability of cheap sugar introduced it to the middle and lower classes. This transformed cuisine in many ways. The extensive culinary and social implications of the availability of inexpensive sugar are well documented by Sidney Mintz (1985) in *Sweetness and Power*. Cheap and available sugar led to the expansion of the domain of acceptable foods, since sugar can be added to foods that are otherwise much less palatable, such as coffee or chocolate, and to enhance the taste of traditional dishes. Finally, in the food-flooded developed world, where the calories signaled by the sweet taste are no longer sought, there is the development of artificial sweeteners, uncoupling the taste and the calories that usually go with it. This allows the experience of the pleasure of sweetness without the calories. All of these extensive advances, with major implications for cuisine and society, are motivated quite directly by the biological predisposition for sweet tastes.

Chocolate

One of the great creations of culture, chocolate, represents a more elaborate version of the amplification illustrated by sugar (P. Rozin, 1982). It illustrates the creation of a “superfood,” motivated by twin biological predispositions

for sweet tastes and fatty textures. The great appeal of chocolate has to do with its sweetness, fatty texture, aroma, and melt-in-the-mouth quality. Importantly, none of these features is obvious in the raw cacao bean, which is very bitter, not particularly aromatic, and does not have a smooth texture. Cacao beans were ground and consumed as a beverage in close to their natural form in several indigenous cultures in Mesoamerica well before the arrival of Cortez (See Coe & Coe, 1996, for the history of chocolate), but this beverage was innately unpalatable and an acquired taste.

Brought to Europe by the early Spanish explorers, cacao was transformed into a luscious food by Western Europeans, and later Americans, in a complex process that involves both modifying the natural product to enhance some of its properties and adding other ingredients (particularly sugar, sometimes milk and vanilla) to improve palatability and produce variety. So, unlike the case for sugar, the cultural evolution of chocolate involved discovery and development of potential in a natural product. The result is a food that is among the most popular in the Western World, and probably, presently, the most craved substance in North America.

The story of chocolate, even more so than sugar, is the story of the amplification and elaboration of biological predispositions. The difference is that the aspects of chocolate that satisfy these predispositions are not apparent in the natural product. It is of particular cultural and psychological interest that although chocolate is raised in tropical areas, particularly West Africa, South America, and parts of Asia, the great desire for it and consumption of it occurs in the very regions that cannot grow it, notably, Europe and North America. This may be explained, in part, on economic grounds; chocolate is expensive, and the tropical countries in which it grows are not wealthy.

Chili Pepper

Chili pepper is probably the most widely used spice in the world. It is eaten on a daily basis, usually as part of a seasoning sauce used with most savory foods, by most tropical and semitropical cuisines in the world. Chili pepper

illustrates the reversal of an innate aversion, a case in which culture overwhelms and reverses a biological predisposition (P. Rozin, 1990).

All chili peppers come from the Americas and were introduced to Europe by the early explorers of the Americas. They spread later to Africa and Asia. The innately aversive irritation of the peppers, caused by a family of chemicals called capsaicins, were bred out of the imported peppers. This probably happened first in Hungary, and the result was what we now call sweet peppers. The sweet peppers became a mainstay of Mediterranean cuisines. But in spite of the availability of such mild peppers, it was the “hot” peppers that spread to tropical and semitropical Africa and Asia. It is a remarkable feature of culinary history that such a “bad tasting” product achieved so much success, particularly when other foods from the Americas, including tomatoes and potatoes, experienced substantial resistance before adoption in Europe and other places.
